It is considered necessary to perform sensitivity studies on those isolates that are considered significant as there is a wide variety of sensitivity patterns. In general, most strains are sensitive and species are sensitive to amikacin and have low MICs to tigecycline (although no specific cut-off point has been established for this antibiotic). *M. abscessus* and *M. chelonae* are usually the most resistant species, and macrolides (except for strains possessing inducible methylase), cefoxitin and amino-glucosides are useful in these cases. *M. fortuitum* complex are usually sensitive to quinolones, aminoglycosides, cotrimoxazole and linezolid, while they are usually resistant to macrolides. Other species such as *M. peregrinum*, *M. mucogenicum* or *M. mageritense* are usually sensitive to numerous antibiotics (Esteban et al., 2012; Brown-Elliott and Philley, 2017).

Leptospira

Introduction

Leptospire belong to the order *Spirochaetales*, family *Leptospiraceae*, genus *Leptospira*. The traditional system divided the genus into two species: the pathogenic *L. interrogans* and the non-pathogenic *L. biflexa*.

Currently, *Leptospira* can be genetically classified based on DNA hybridization technique into at least 20 species: pathogenic species, intermediate, or saprophytic (Fouts et al., 2016; Levett, 2015). *Leptospira* species are further divided into hundreds of serovars, defined by cross-agglutinin absorption testing with rabbit antiserum (Naze et al., 2015). For convenience, serovars are often grouped into serogroups, which have no taxonomic significance but can be identified by microscopic agglutination testing (MAT) of acute and convalescent serum from infected patients (Haake and Levett, 2015). The genetic classification of *Leptospira* does not correlate with the phenotypic classification because serovars of the same serogroup may be distributed between different species.

Pathogenic species causes leptospirosis. The classical description of leptospirosis is that of Weil's disease, an acute, febrile and sometimes epidemic illness characterized by jaundice, splenomegaly and nephritis. Some infected persons, however, may have no symptoms at all.

Transmission

Leptospirosis is a zoonotic disease transmitted directly or indirectly from animals to humans (Faine, 1982). About 160 mammalian species have been identified as natural carriers of pathogenic leptospire. These include feral, semi-domestic and farm and pet animals as important infection sources. The disease occurs worldwide but is more common in tropical and subtropical areas. Infection usually results from direct or indirect exposure to the urine of infected animals, or indirect exposure through contaminated soil and water (Faine, 1982). It is an occupational hazard for many people who work outdoors or with animals, such as farmers and veterinarians. Leptospirosis has also been associated with swimming, or people who work in contaminated water. Human-to-human transmission occurs only very rarely. Transmission may occur via sexual contact and mother's milk. In-uterus transmission can lead to reproductive failures such as abortion.

Clinical significance

Leptospire can enter the body through cuts and abrasions in the skin, through the mucosa (conjunctiva, respiratory tract); They can occasionally enter in the human body via the inhalation of droplets of urine or via drinking-water.

After infection, leptospire appear in the blood and invade practically all tissues and organs. They are subsequently cleared from the body by the host's immune response.

The incubation period for leptospirosis ranges from 2 to 20 days, with an average of 10 days, but in rare cases very long incubation periods have been reported (Faine, 1982; Kelly, 1992). The infection is associated with a very broad spectrum of severity, ranging from subclinical illness to a self-limited biphasic illness, and a severe potentially fatal illness. Biphasic systemic illness has been seen in approximately 90% of infection. The initial, or systemic phase begins abruptly with fever, headache, myalgia, nausea and vomits. Skin rash, pharyngitis and conjunctival injection develops in the first or second days. Often the skin is warm and erythematous, with the patient complaining of feeling warm. Psychological changes are often seen, with patients feeling depressed, confused, aggressive and sometimes psychotic. After 3–7 days, patient improves for 1–3 days, reflecting the beginning of the immune response; the second or immune phase begins. Immune phase is generally shorter and slighter than systemic phase. The initial symptoms and fever return, accompanied with chest and abdominal pain, some renal problems and psychological changes. Meningitis and leptospire in urine are the most important features.

Distinct phases of illness may not be observed, particularly for patients with severe disease (Levett, 2001). About 10% of patients develop icteric severe leptospirosis. Symptoms are the same as for the mild type but more pronounced, and multiple organs are damaged—liver and kidney failure can appear, leading to jaundice and may cause potentially fatal conditions such as Weil's syndrome and the emerging Severe Pulmonary Hemorrhagic Syndrome (SPHS).

In a recent systematic review, mortality was low in patients with anicteric leptospirosis or meningitis (median, 0%), but mortality increased with patient age and was higher in patients with jaundice (19.1%) or renal failure (12.1%) (Taylor et al., 2015).

Immune response

Humans react to an infection by leptospire by producing specific anti-*Leptospira* antibodies. In the initial phase, patients with leptospirosis may produce antibodies that react with several serovars (cross-reaction) but in the course of weeks or months cross-reactive antibodies gradually disappear, while serogroup- and serovar-specific antibodies often persist for years. The genus-specific antibodies usually remain detectable for months, the serovar specific antibodies for years.

Seroconversion may occur as early as 5–7 days after the onset of disease but sometimes only after 10 days or longer. IgM class antibodies usually appear somewhat earlier than IgG class antibodies, and generally remain detectable for months or even years but at low titer.

Diagnostic

Laboratory diagnosis included: culture, detection of specific immune response and detection of specific DNA by polymerase chain reaction (PCR).

Culture and isolation

During the systemic phase, the most suitable sources to culture are blood and CSF. After the first 7 days of illness the most appropriate source for isolation of leptospira is urine.

1 or 2 drops of blood are inoculated into several tubes, each containing 5 mL of a suitable medium semisolid medium such as Fletchers, Ellinghausens or polysorbate 80 (Faine, 1982; Sulzer and Jones, 1978). Inoculate 3–5 tubes. For CSF, a volume of 0.5 mL of sample per 5 mL of medium is recommended. For urine one drop of undiluted urine is inoculated into a tube containing 5 mL of culture medium. Alternatively, urine samples may be centrifuged and the pellet resuspended in medium, after which 10-fold serial dilutions are made immediately in 1 or 2 additional tubes. Cultures should be incubated at 30 °C and examine a drop of culture by dark-field microscopy regularly for a period of 4–6 months, although leptospire are usually detectable in positive cultures within 1–2 weeks.

Isolation of *Leptospira* spp. from clinical samples has low diagnostic sensitivity, requires specialized expertise, and most importantly takes too long to be of use to the treating team (Picardeau, 2013).

Serological test

Anti-*Leptospira* antibodies become detectable around day of illness 5–7.

Microscopic Agglutination Test (MAT) and Enzyme-linked Immunosorbent Assay (ELISA) are the methods generally used in laboratory diagnosis.

The MAT is a micro-agglutination test carried out using live antigen pools, and detects both immunoglobulin M (IgM) and immunoglobulin G (IgG) class agglutinating antibodies. Serially diluted from the dilution of 1:100, serum specimens were added to the antigen suspension in 96 well round bottomed microtiter plates. The plates are gently shaken, covered and incubated for 2 h at room temperature. Agglutination was examined using dark field microscopy. The reciprocal of the highest dilution agglutinating at least 50% of the *Leptospira* organisms, was considered the end point.

A serologically confirmed case to leptospirosis is defined by a fourfold rise in MAT titer between acute-phase and convalescent serum samples run in parallel. A titer of at least 1:800 with compatible symptoms is strong evidence of recent or current infection (Faine, 1982).

Limitation to MAT is the requirement for paired acute and convalescent serum samples for optimal performance, low sensitivity when acute serum samples are tested (Cumberland et al., 2001), and cross-reactivity with Lyme disease, legionellosis, autoimmune disease, and viral hepatitis (Bajani et al., 2003) and in regions where leptospirosis is common, there may be a substantial proportion of the population with elevated titers.

The IgM ELISA test detects early production IgM and therefore can become positive earlier than the MAT, but suffers from both false positive and false negative problems. IgM-ELISA's sensitivity ranges from 48% to 100% and specificity ranges from 88.6% to 98% (Niloofa et al., 2015).

An immunochromatographic test is available that identifies specific IgM and provides results in 15 min with sensitivity and specificity similar to the ELISA tests (Niloofa et al., 2015).

Polymerase chain reaction

A variety of molecular techniques, including conventional and real-time polymerase chain reaction (PCR), have been developed for the specific detection of pathogenic *Leptospira* species (Jesse et al., 2016). PCR allows the diagnosis in early stages, before the appearance of specific antibodies. Specific DNA can be detected from blood, CSF, urine and tissue although serum is the optimal sample. A limitation of PCR-based diagnosis of leptospirosis is the inability of most PCR assays to identify the infecting serovar (Bal et al., 1994).

A study on 103 patients of meningitis of unknown cause showed that 39.08% were positive by PCR, 3.88% by ELISA & 8.74% by MAT (Romero et al., 1998). The use of real-time RT-PCR for testing serum/plasma and cerebrospinal fluid, when available, may improve the detection of *Leptospira*.

Treatment

Antimicrobial therapy is indicated for the severe form of leptospirosis, but its use is controversial for the mild form of leptospirosis.

Antibiotic therapy is most effective when begun early in the infection.

In severe illness, one of the following is recommended (Brett-Major and Coldren, 2012):

- Penicillin G 5–6 million units IV every 6 h.
- Ampicillin 500–1000 mg IV every 6 h.

In less severe cases, one of the following may be given for 5–7 days:

- Doxycycline 100 mg orally every 12 h.
- Ampicillin 500–750 mg orally every 6 h.
- Amoxicillin 500 mg orally every 6 h.

In severe cases, supportive care, including fluid and electrolyte therapy, is also important.

Prevention

Rodents and fresh water are the primary risk factor for leptospirosis and once dispersed through the urine of contaminated animals, such as rats, the bacteria can survive for up to 6 months in fresh water or a humid location. There are several steps to help prevent getting leptospirosis. These include: Avoid contact with animal urine or body fluids, do not swim in, walk in, swallow or submersing head in potentially contaminated freshwater (rivers, streams), wear protective clothing or footwear near soil or water that may be contaminated with animal urine and keep rodent populations (rats and mice) or other animal pests under control.

Some studies have shown that chemoprophylaxis with doxycycline might be effective in preventing clinical disease and could be considered for people at high risk and with short-term exposures. But a systematic review concluded that regular use at 200 mg weekly was associated with nausea and vomiting, and there was no clear benefit for reducing the risk of leptospirosis (Brett-Major and Lipnick, 2009).

Borrelia

Introduction

Borrelia species are members of the family *Spirochaetaceae*, so present the characteristic spirochete shape. *Borrelia* species have an outer membrane and an inner membrane, with axial filaments called endoflagella in their periplasmic space. The axial filaments rotate in this space, propelling the bacterium. *Borrelia* includes several species transmitted by lice and ticks and causing relapsing fever (*B. recurrentis* and others) and Lyme disease (*B. burgdorferi*) in humans.

Lyme borreliosis

B. burgdorferi sensu lato (s.l.) species complex causes Lyme borreliosis (LB), which are transmitted by several species of *Ixodes* ticks (Stanek et al., 2012).

The *B. burgdorferi* complex comprises at least 15 genospecies worldwide; human infections are caused by three *B. burgdorferi* sensu lato genospecies: *B. garinii*, *B. afzelii*, and *B. burgdorferi* sensu stricto. All three species cause LB in Europe, whereas only *B. burgdorferi* sensu stricto causes LB in the United States (European Centre for Disease Prevention and Control, 2016).

Two other pathogenic genospecies, less frequent, have been identified in Europe: *B. bavariensis*, associated with neurological complications and *B. spielmanii*. *B. valaisiana* and *B. lusitaniae* rarely cause disease in humans.

LB is the most prevalent tick-transmitted infection in temperate areas of Europe, North America and Asia. The mean annual number of LB notified cases in Europe is more than 65,400 with a strong heterogeneity in spatial distribution: the level of antibodies to *B. burgdorferi* s.l. is highest in residents of northern and central countries and lowest in those in the southern countries. Countries with high incidence rates include Slovenia, Germany and Austria, the Baltic coastline of southern Sweden, and some Estonian and Finnish islands (Rizzoli et al., 2011).

Transmission

The vectors of *B. burgdorferi* s.l. are hard ticks of the genus *Ixodes*. The main vector of Lyme borrelia in Europe is *Ixodes ricinus*, whereas *Ixodes persulcatus* is the main vector in Asia. *Ixodes scapularis* is the main vector in northeastern and upper Midwestern United States and *Ixodes pacificus* is the vector in Western United States (Stanek et al., 2012).

Ticks normally feed on animals, ground-feeding birds, or reptiles. Humans are a secondary blood source. The Lyme disease ticks can attach to any part of the human body but are often found in hard-to-see areas such as the groin, armpits, and scalp. Most humans are infected through the bites of immature ticks called nymphs. Nymphs are tiny (less than 2 mm) and difficult to see. The prime seasons for human tick bites are late spring and summer. Adult ticks can also transmit Lyme disease bacteria, but they are much larger and are more likely to be discovered and removed before they had time to transmit the bacteria. Adult *Ixodes* ticks are more active during the cooler months of the year.

Clinical presentation

LB can involve several organs and may have different clinical presentations. The clinical expression of borreliosis is divided into three stages (Stanek et al., 2012; European Centre for Disease Prevention and Control, 2016).

Stage I: Early manifestations or erythema migrans

Erythema migrans (EM) occurs in about 80–90% of cases, few days to several weeks after the infection. It is an erythematous rash that gradually expands from the site of a tick bite and is not significantly raised or painful. EM is often accompanied by influenza-like symptoms such as fever and sweats, chills, fatigue, neck pain or stiffness, headaches, joint or muscle pains. Less common are backache, nausea and vomiting, sore throat, lymphadenopathy, and splenomegaly.

Without therapy, erythema migrans typically fades within 3–4 weeks.

Stage II: Early disseminated stage

If the infection remains untreated, bacteria can spread to other tissues and organs. The second stage of the disease causes more severe manifestations that can involve the skin, nervous system, joints, or heart.

Neuroborreliosis (NB) is the main complication of LB (it appears in 10% of patients with EM). Most common are lymphocytic meningitis or meningoencephalitis, or neuritis. Other uncommon features of disseminated infection include multiple erythema migrans, intermittent arthritis and carditis. These also present within a few weeks to several months of infection.

Myocardial abnormalities appear about 8% of patients in weeks of EM. They include fluctuating degrees of atrioventricular block and, rarely, myopericarditis.

Stage III: Late stage

The late stage begins months to years after initial infection. The late or disseminated LB includes acrodermatitis chronica atrophicans (ACA), arthritis, or more severe stages of NB.

Arthritis develops in about 60% of patients within several months, occasionally above to 2 years, of disease onset. Intermittent swelling and pain in a few large joints, especially the knees, typically recur for several years. Affected knees commonly are much more swollen than painful; they are often hot but rarely red. Baker cysts may form and rupture. Malaise, fatigue, and low-grade fever may precede or accompany arthritis attacks. In about 10% of patients, knee involvement is chronic (unremittent for ≥ 6 months).

Other late findings (occurring years after onset) include an antibiotic-sensitive skin lesion (acrodermatitis chronica atrophicans) and chronic central nervous system abnormalities, either polyneuropathy or a subtle encephalopathy with mood, memory, and sleep disorders.

Some patients have symptoms such as fatigue, headache, joint and muscle aches, and cognitive problems after successful antibiotic treatment (post-treatment Lyme disease syndrome).

Stage 2 and stage 3 symptoms may be the first signs of Lyme disease in people who didn't have a rash or other symptoms of early infection.

Laboratory diagnosis**Culture**

B. burgdorferi s.l. strains have been isolated from the blood, cerebrospinal fluid (CSF) and synovial fluid in complex media. Culture sensitivity depends on sample and clinical manifestation. The relative complexity of the culture makes it available in specialized laboratories.

Nucleic acid amplification techniques

Nucleic acid amplification techniques are available for the detection of genospecies of Lyme borrelia in specialized laboratories. This method cannot establish whether or not an infection is active because polymerase chain reaction (PCR) detects borrelial DNA of both viable and non-viable organisms.

PCR testing of CSF or synovial fluid is often positive when those sites are involved. PCR for detection of borrelial DNA in synovial fluid specimens is positive in up to about 80% of untreated patients with Lyme arthritis (Aguero-Rosenfeld et al., 2005; Cerar et al., 2010). The sensitivity of PCR in CSF tends to be much lower than it is in synovial fluid (Wilske et al., 2007). It should be emphasized that a negative result for PCR does not exclude active infection.

PCR on blood or urine samples are not recommended for clinical use (Stanek et al., 2012).

Serology

Serological testing is the principal means of laboratory diagnosis of Lyme disease. Assays available for serology are immunofluorescence, enzyme-linked immunosorbent assay (ELISA), chemiluminescence and immunoblot. Third generation immunoassays use recombinant or synthetic antigens like C6, OspC, p100, p18, p41 and VlsE.

Serological assays for antibodies to *B. burgdorferi* are negative frequently at EM stage, and typical erythema is usually diagnosed clinically. In atypical EM cases serologic evidence of infection is best obtained by testing of paired acute- and convalescent-phase serum samples.

Serum samples from persons with disseminated or late-stage LB almost always have a strong IgG response to *Borrelia* antigens.

Serodiagnosis of LB is currently based on a sensitive screening assay and subsequent confirmation by an specific immunoblot system. Most screening assays use VlsE or C6 as a single antigen for detection of specific IgG antibodies. OspC (as a single antigen or in a mixture with other antigens) is used for detection of specific IgM antibodies.

If the screening test result is positive, it should be followed up by a confirmatory test. The immunoblot with recombinant antigens is the method of choice because it allows a reliable differentiation between individual antigens.

In the first 4 weeks of disease onset (early LB), both IgM and IgG should be tested. If only IgM bands are detected on immunoblot, especially in persons with illness greater than 1 month's duration, the results are often false positive.

However, more recently, the results of several studies suggest that the screening test that use Vlse and OspC as show sufficiently sensitivity and specificity to replace the two-step test principle (Steere et al., 2008; Branda et al., 2011; Moore et al., 2016).

Serological testing for neurological Lyme disease is based on demonstrating intrathecal synthesis of *Borrelia*-specific antibodies in CSF. IgG serology assay is performed on CSF and paired serum and the results compared (Stanek and Strle, 2018).

Immunological tests for cellular response: These are tests that measure cellular immunological response. Examples are T-cell activity and decrease or increase of certain lymphocyte subpopulations. These tests are labor intensive, require laboratory expertise and are still under development (Stanek and Strle, 2018).

Treatment

People treated with appropriate antibiotics in the early stages of Lyme disease usually recover rapidly and completely. Antibiotics commonly used for oral treatment include doxycycline, amoxicillin, or cefuroxime axetil. Macrolides such as azithromycin are used as second-line treatment.

Neurological or cardiac forms of illness may require intravenous treatment with antibiotics such as ceftriaxone or penicillin. More recent studies suggest that oral doxycycline treatment of NB is as effective as intravenous ceftriaxone (Ogrinc et al., 2006). Antibiotics should be administered for 2 weeks in cases of early localized and early disseminated disease. For chronic manifestations, a 4-week course is recommended. Pregnant women with Lyme borreliosis receive the same antibiotic treatment as women who are not pregnant, except that doxycycline should be avoided.

Antibiotic treatment and doses are as follows (Wormser et al., 2006):

In erythema migrans, doxycycline (100 mg twice per day) or amoxicillin (500 mg³ times per day) or cefuroxime axetil (500 mg twice per day). Alternative: Clarithromycin 500 mg orally twice per day or azithromycin 500 mg orally per day. Duration of treatment must be 14–21 days, except for azithromycin (7–10 days).

In meningitis or cardiac manifestation, doxycycline 100–200 mg orally twice a day or ceftriaxone 2 g IV once a day or cefotaxime 2 g IV q 8 h or penicillin G 3–4 million units IV q 4 h. Duration of treatment will be 14–28 days.

In arthritis, amoxicillin 500 mg orally three times a day, or doxycycline 100 mg orally twice a day or cefuroxime axetil 500 mg orally twice a day. Duration of treatment will be 28 days.

Prophylaxis and prevention

Transmission of *B. burgdorferi* does not usually occur until the infected tick has been in place for >36 h. Thus, searching for ticks after potential exposure and removing them promptly can help prevent infection.

Antibiotic prophylaxis (doxycycline) to prevent Lyme disease after a recognized tick bite is recommended if, the tick is estimated to have been attached ≥ 36 h and patients have visited an area where $\geq 20\%$ of these ticks are infected with *B. burgdorferi* (Wormser et al., 2006).

Treponema

Introduction

The genus *Treponema* consists of pathogenic and non-pathogenic spirochaetes. Human diseases caused by the treponemes are syphilis (*Treponema pallidum* subsp. *pallidum*), endemic syphilis (*T. pallidum* subsp. *endemicum*), yaws (*T. pallidum* subsp. *pertenue*) and pinta (*T. carateum*). While syphilis is a venereal disease, the remaining are not sexually transmitted.

Syphilis

Syphilis is a systemic infection usually contracted through sexual activities, and is characterized by an extraordinary variety of clinical manifestation. Vertical transmission can occur in the first 4 years after infection.

According to the WHO, in 2014 there were a rate of 25.1 cases per 100,000 adults. Regions with the highest incidence were Africa and western Pacific (European Centre Disease Prevention and Control, 2018). In Europe, 29,365 cases were reported in 2016 with an incidence of 6.1 cases per 100,000 inhabitants (European Centre Disease Prevention and Control, 2018).

Depending on the time elapsed from infection to diagnosis, it is classified as early syphilis or late syphilis. Early syphilis is syphilis that has been acquired in the last year and late syphilis is syphilis acquired more than a year previous. Early syphilis includes primary syphilis, secondary syphilis and early latent syphilis. Late syphilis includes late latent syphilis and tertiary syphilis (European Centre Disease Prevention and Control, 2018). For WHO early syphilis is that acquired in the last 2 year.

Clinical manifestations

Early syphilis

After an incubation period of 9–90 days a primary lesion or chancre appears, often at the site of infection. It is usually solitary, indurated, painful and a serous exudate is formed in the center. The exudate have many spirochetes and is highly infectious. The chancre usually lasts 3–6 weeks and disappears regardless of treatment. During this stage the treponemes spread throughout the body via the lymphatic system and the blood. Atypical manifestations include multiple painful, destructive, usually extragenital (most frequently oral) chancres, and sometimes without chancre.

Secondary syphilis occurs in 25% of untreated infected individuals and begins between 2 and 8 weeks after the onset of the initial chancre. There can be fever, anorexia and arthralgias. The central nervous system can be affected and in fact, any organ can be affected. It often presents as a disseminated mucocutaneous rash and generalized lymphadenopathy. The lesions can be macular, maculopapular, papular or pustular, with no vesicular lesions. The different morphologies can be present at the same time and affect any cutaneous location, especially palms of the hands and soles of the feet. Lesions may appear on the tongue, mucous membranes and scalp (alopecia). In relapses, secondary syphilis lesions are usually less florid.

In latent syphilis, which can persist over time, there are no clinical manifestations, only serological reactivity.

Tertiary syphilis

Late or tertiary syphilis would appear 10–30 years after the infection began and it is divided into gummatous syphilis (15% of patients), cardiovascular syphilis (10%) and late neurological complications (7%). Most people with untreated syphilis do not develop tertiary syphilis.

Neurosyphilis is the infection of the central nervous system by *T. pallidum* and this can happen during any of the stages of syphilis. There are different forms of neurosyphilis: symptomatic, asymptomatic meningitis and meningovascular neurosyphilis, the most serious form of meningeal neurosyphilis. In late disease there is usually overlap of meningovascular and parenchymal involvement. Symptoms of neurosyphilis include headache, difficulty coordinating muscle movements, paralysis, and mental disorder.

Congenital syphilis

Congenital syphilis (CS) appear when bacteria *T. pallidum* is transmitted from a pregnant woman to her fetus. Overall risk of transplacental infection of the fetus is about 60–80%, and likelihood is increased during the 2nd half of the pregnancy. Untreated primary or secondary syphilis in the mother usually is transmitted, but latent or tertiary syphilis is transmitted in only about 20% of cases. Infection can result in stillbirth, prematurity, or a wide spectrum of clinical manifestations.

In infected neonates, manifestations of syphilis are classified as early congenital (i.e., birth through age 2 year) and late congenital (i.e., after age 2 year).

Clinical manifestations in early congenital syphilis: in untreated infants usually appear by 3 months of age, most often by 5 weeks. An infant or child (aged less than 2 years) may have signs such as: hepatosplenomegaly, rash, condyloma lata, snuffles, jaundice, pseudoparalysis, anemia or edema.

Clinical manifestations in late congenital syphilis includes: Hutchinson's triad (Hutchinsons teeth, interstitial keratitis, and eighth nerve deafness), facial features (frontal bossing, saddle nose, short maxilla, protuberant mandible), interstitial keratitis secondary glaucoma, corneal scarring, optic atrophy, sensorineural hearing loss associated with late congenital syphilis typically develops suddenly at 8–10 years old and often accompanies interstitial keratitis, Hutchinson teeth, gummas in the skin or mucous membranes, intellectual disability skeletal and hematologic manifestation.

Laboratory diagnosis

Direct detection methods include the detection of *T. pallidum* by microscopic examination of samples from lesions or nucleic acid amplification methods such as PCR. Indirect diagnosis is based on serological tests for the detection of antibodies and is indicated for routine diagnosis of suspected syphilis cases, monitoring of treatment of diagnosed syphilis, and as part of prenatal screening, and donor screening.

Direct detection of *Treponema pallidum*

Darkfield microscopy

Exudates and fluids from a chancre or lymph node aspirate are examined as a wet mount using dark-field microscopy to directly visualize spirochetes. This technique requires a trained, experienced microscopic and is subject to both false positive and (many) false negative result (Wheeler et al., 2004).

Nucleic acid amplification methods

It is widely accepted that routine PCR could be an effective supplement for early diagnosis, especially suitable for the clinical sample cases, such as chancre secretions and other lesions where contamination with comensal treponemes is likely (Janier et al., 2016; Zhou et al., 2019). Additionally, routine PCR has been reported to detect atypical cases in tonsillar, vertebral, and ocular syphilis

(Zhou et al., 2019). CSF PCR is considered to have little value for the diagnosis of neurosyphilis because it has low sensitivity and specificity (Arando and Otero, 2019).

Serological test

There are two categories of tests for syphilis: non-treponemal tests and treponemal tests. Antibody to non-treponemal antigens is found in active disease and the levels subside after successful treatment, while *Treponema*-specific antibodies persist for a long time after the infection has been successfully treated. Both tests are needed for aiding the diagnosis of syphilis.

Non-treponemal tests (NTT): these detect antibodies to antigens such as cardiolipin and lecithin released from the damaged host cells, as well as lipoprotein-like material released from the *Treponema* and are not specific for syphilis. The most common NTT are the Rapid Plasma Reagin (RPR) and Venereal Disease Research Laboratory (VDRL). The RPR tests are macroscopic agglutination tests and require no microscope and the VDRL tests are microflocculation tests and are read under a microscope. NTT are often used as a screening test against syphilis, because are cheap, simple and allow semiquantification; these techniques help to establish the phase of the infection and are generally considered to be sensitive in early syphilis and poor sensitivity in the late stage of infection (Table 1). NTT are used to monitor patients response to treatment. RPR titers are usually higher than those of the VDRL. The sensitivity of serological tests for syphilis is detailed in Table 1 (data from Ratnam, 2005; Park et al., 2019).

These tests can have a high false-positive rate, especially in low prevalence populations. False-positive results are usually, but not always, of low titer (<1:8) and occur due to autoimmune disease, drug addiction, acute viral infections, recent immunizations, or age (10% of people over 80 years of age have false-positive tests results). False-negative reactions can occur due to the prozone phenomenon, especially in secondary syphilis.

Treponemal test (TT): include the FTA-Abs (fluorescent treponemal antibody absorption) test, TPHA (*Treponema pallidum* Hemagglutination), TPPA (*Treponema pallidum* particle agglutination), EIA (enzyme immunoassays), Immunoblot, CLIA (chemiluminescence immunoassay) and rapid treponemal assays. TT detect antitreponemal antibodies and indicate exposure to syphilis during the patient's lifetime. A positive result, however, does not mean the patient currently has untreated syphilis. Treponemal tests have equivalent sensitivity but greater specificity for *T. pallidum* infection compared to non-treponemal tests. Positive results from both tests support a diagnosis of syphilis with a very high positive predictive value. A treponemal test remains positive even after successful treatment of the disease and cannot be used to monitor therapy.

The sensitivity of serological tests for syphilis is detailed in Table 1 (data from Ratnam, 2005 and Park et al., 2019).

Syphilis screening

The traditional syphilis testing algorithm starts with a NTT test followed by a TT if the first test is reactive, but in many laboratories the new reverse algorithm is used. The initial test performed is a treponemal antibody test (EIA or CLIA). If the specimen is reactive, a NTT semi-quantitative RPR or VDRL (titer) will be performed. If the NTT test is reactive, the results are interpreted as consistent with current or past syphilis infection. If the NTT is non-reactive, a second treponemal test (TPHA or TPPA) is performed and charged. If this test is reactive, the results indicate past or potential early syphilis infection. If it is non-reactive, the presence of treponemal antibodies is not confirmed and the testing algorithm is inconclusive for syphilis infection. This could indicate that the initial treponemal test was a false positive. The reverse algorithm is illustrated in Fig. 1.

Special circumstances

Neurosyphilis: the VDRL is the test of choice for cerebrospinal fluid (CSF) to assist in the diagnosis of neurosyphilis (Kent and Romanelli, 2008; Marra, 2004). It is of particular importance that CSF is not contaminated with blood. VDRL is highly specific but insensitive, therefore, a positive can be used for diagnosis but a negative does not rule out neurosyphilis. The FTA-Abs treponemal

Table 1 Sensitivity (%) of serological test for syphilis.

Stage of syphilis	Test			
	Non-treponemal		Treponemal	
	VDRL/RPR	FTA-ABS	TPHA	CLIA
Primary	80–86	79	95	96
Secondary	95	100	100	100
Latent	97	100	100	98

VDRL, Venereal Disease Research laboratory; RPR, Rapid Plasma Reagin; FTA-ABS, Fluorescent treponemal antibody absorption; TPPA, *Treponema pallidum* particle agglutination; CLIA, Chemiluminescence immunoassay.

Data from references Ratnam S (2005) The laboratory diagnosis of syphilis. *Canadian Journal of Infectious Diseases and Medical Microbiology* **16**(1): 45–51. and Park IU, Fakile YF, Chow JM, Gustafson KJ, Jost H, Schapiro JM, Novak-Weekley S, Tran A, Nomura JH, Chen V, Beheshti M, Tsai T, Hoover K, Bolan G (2019) Performance of Treponemal Tests for the Diagnosis of Syphilis. *Clinical Infectious Diseases* **68**: 913–918.

Fig. 1 Syphilis serology algorithm in Virgen de las Nieves University Hospital.

test is another test that has been used in CSF fluid. This test has high sensitivity and low specificity; a negative test is consistent with the absence of neurosyphilis. False-positive CSF results are common with the FTA-Abs test as a consequence of passive diffusion of treponemal antibodies through blood-brain barrier. PCR methods are not very helpful due to their low sensitivity and specificity in CSF.

Neonatal syphilis: Newborn infants should not be discharged from the hospital without determination of the mother's serologic status for syphilis. Testing of the infant's blood is inadequate for screening because false-negative and false-positive results can occur. Maternal IgG antibodies are passively transferred across the placenta. Therefore, a positive syphilis IgG or FTA-Abs test (both treponemal tests) is not conclusive of active syphilis infection; the NTT on the infant must be positive as well. The tests performed on the infant should be the same as those performed on the mother to enable comparison of titer results: if the infant's titer was higher than that of the mothers, then the infant had congenital syphilis. A lower titer in the infant's serum than in the mother does not rule out congenital syphilis (Norris and Larsen, 1995).

Treatment

The recommended treatment at all stages of this disease is penicillin benzathine administered parenterally. In primary, secondary or early-stage latent syphilis (by definition, less than a year), the recommended treatment is a single injection IM of Benzathine penicillin G 2.4 million units. Additional doses of 2.4 million units should be given 7 and 14 days later for late (>1 year) latent syphilis or latent syphilis of unknown duration because treponemes occasionally persist in the CSF after single-dose regimens. Treatment is the same regardless of HIV status.

For non-pregnant patients with a significant penicillin allergy (anaphylactic, bronchospastic, or urticarial), the first alternative is doxycycline 100 mg orally twice a day for 14 days (28 days for late latent syphilis or latent syphilis of unknown duration). Azithromycin 2 g orally in a single dose is effective for primary, secondary, or early latent syphilis caused by susceptible strains.

For pregnant women with syphilis penicillin is the only recommended treatment. Women who are allergic to penicillin can undergo a desensitization process that may allow them to take penicillin.

The treatment for neurosyphilis and ocular syphilis is penicillin G sodium 3,000,000–4,000,000 IU intravenously every 4 h (18–24 million IU/day) for 10–14 days.

For congenital syphilis Centers for Disease Control and Prevention (CDC) recommend aqueous crystalline penicillin G 50,000 units/kg IV q 12 h for the first 7 days of life and q 8 h thereafter for a total of 10 days or procaine penicillin G 50,000 units/kg IM once/day for 10 days. If ≥ 1 day of therapy is missed, the entire course must be repeated.

Most patients with primary or secondary syphilis, especially those with secondary syphilis, have a Jarisch-Herxheimer reaction within 6–12 h of initial treatment. Signs and symptoms include a fever, chills, nausea, achy pain and a headache. This reaction usually doesn't last more than 1 day.

Follow-up

Patients with early syphilis who have been treated with appropriate doses and preparations of benzathine benzylpenicillin should be evaluated clinically and serologically, using a non-treponemal test, after 3 months to assess the results of therapy. A second evaluation should be performed after 6 months and, if indicated by the results at this point, again after 12 months. Following adequate therapy for primary and secondary syphilis, there should be at least a fourfold decline in titer by the third or fourth month and an eightfold decline in titer by the sixth to eighth month. Patients treated in the latent or late stages may show a more gradual decline in titer, and low titers persist in approximately 50% of these patients. This persistent titer does not signify treatment failure (Norris and Larsen, 1995).

Repeat treatment should be considered when clinical signs or symptoms of active syphilis persist or recur or there is confirmed increase in the titer of a non-treponemal test.

Patients should be re-treated with the schedules recommended for syphilis of more than 2 years duration. In general, only one re-treatment course is indicated because adequately treated patients often maintain stable, low titers of non-treponemal tests.

Bejel, pinta and yaws

Bejel, pinta, and yaws (endemic treponematoses) are chronic, tropical, non-venereal spirochetal infections spread by body contact.

Yaws (also known as frambesia or pian) is caused by *T. pallidum* subspecies *pertenue*. Transmission occurs mainly in poor communities in warm, humid tropical regions of Africa, Asia, Latin America and the Pacific.

Bejel is caused by *T. pallidum* subspecies *endemicum*. Transmission occurs principally in the Sahel region of Africa and the Arabian Peninsula.

Pinta is caused by *T. carateum*. Transmission occurs only in the American region.

They may be differentiated by clinical manifestations, geographic distribution, and molecular diagnostic testing.

Bejel, yaws, and pinta are spread by any close contact with the skin of an infected person. Bejel also may be spread by mouth-to-mouth contact or when eating utensils are shared. Also unlike syphilis, bejel, yaws, and pinta are not spread through contact with contaminated blood or from mother to fetus during pregnancy.

Clinical manifestations

Bejel

Bejel usually begins in childhood as a small mucous patch, often on the interior of the mouth, followed by the appearance of raised, eroding lesions on the limbs and trunk.

Periostitis (inflammation) of the leg bones is commonly seen, and gummas of the nose and soft palate develop in later stage.

Yaws

After an incubation period of several weeks, begins at the site of inoculation as a red papule that enlarges, and ulcerates (primary yaws). Within next 3–6 weeks generalized eruption develops that resembles condylomata lata of secondary syphilis (secondary yaws). During the next 5–10 years, destructive lesions (tertiary yaws) may develop in skin, mucous membrane, and bone.

Pinta

The skin is the only organ involved in pinta. Lesions begin at the inoculation site as a small papule that enlarges and becomes hyperkeratotic; pinta usually progresses and some lesions become slate blue or depigmented.

Diagnosis

Diagnosis of endemic treponematoses is based on the typical appearance of lesions in people from endemic areas. Serologic test for syphilis, NTT and TT are positive; differentiation from venereal syphilis is clinical.

Treatment

Yaws is treated with 1 dose of penicillin benzathine 1.2 million units IM. Children <45 kg should receive 600,000 units IM. A single dose of azithromycin 30 mg/kg orally (maximum 2 g) is the preferred treatment because of the ease of administration.

Alternative agents for treatment of endemic treponematoses in non-pregnant adults include doxycycline (100 mg orally twice daily for 15 days) or tetracycline (500 mg orally four times a day for 15 days) (Perine et al., 1984).

Introduction

Ureaplasma spp. and *Mycoplasma* spp. belong family *Mycoplasmataceae*, order *Mycoplasmatales* and to the class *Mollicutes*, which means “soft skin” since it is composed of microorganisms whose main characteristic is the absence of cell wall and presences of sterols in the cell membrane. This characteristic differentiates them from the rest of the prokaryotes, phylogenetically, *Mycoplasmas* are more closely (Kashyap and Sarkar, 2010). *Mycoplasmas* are the smallest free-living microorganisms, both in cell size (0.2–0.8 nm), and in the size of their genome, the smaller being that of *M. genitalium* with only 381 genes and 580 kb. An intimate microorganism-host relationship is established that manifests as surface parasitism with epithelial cells and immune system cells and as an intracellular location, in some species (Acosta et al., 2011b).

Mycoplasmas take pleomorphic forms. Some of them can pass 45 µm filters, so they were originally thought to be viruses. However, these microorganisms are divided by binary fission, some of them can grow in acellular artificial media and contain RNA and DNA. They behave like optional aerobics (except *M. pneumoniae* which is strict aerobic) and need exogenous sterols for growth. Their generation time is high, so they need prolonged incubation to be detected. The extremely small size (150–200 nm) and its limited metabolic and biosynthetic capabilities are responsible for many of the biological characteristics of the organisms. It explains the parasitic and saprophytic existence of the organisms and its fastidious growth requirements which may complicate its detection by culture (Kashyap and Sarkar, 2010; Zhou et al., 2018).

Ureaplasma urealyticum was first isolated in 1954, 17 years later than *Mycoplasma hominis*. Subsequently, with the development of nucleic acid amplification (PCR) techniques, other species such as *Mycoplasma genitalium* and *Ureaplasma parvum*, formerly considered a serovariety of *U. urealyticum*, could be differentiated. To date, *Ureaplasma* spp. consists of 14 serovars which could be divided into two species, *Ureaplasma parvum* (UPA) and *Ureaplasma urealyticum* (UUR), based on differential growth responses to manganese, 16S rRNA gene sequences, the 16Se23S rRNA intergenic region, urease gene, and differences in the multiple-banded antigen (MBA) genes. UPA comprises four serovars (1, 3, 6, and 14), while UUR includes the remaining 10 serovars (Feng et al., 2016; Zhou et al., 2018).

Epidemiology

They are widely distributed in nature and, today, the growing number of established species approaches 200, many of which behave like diners, mainly in the oropharynx and genitourinary tract, while others are pathogenic to man, animals and plants.

In humans, 14 species have been isolated, 12 belong to the genus *Mycoplasma* and 2 species (*Ureaplasma biovar parvum* and *Ureaplasma urealyticum*) belong to the genus *Ureaplasma*. Six of the 14 species have the genitourinary tract as their main place of colonization, so they are known as genital mycoplasmas (Latino et al., 2018).

Ureaplasma spp. has been isolated in 30–80% of vaginal/cervical samples from sexually active women (Castellano-González et al., 2007; Leli et al., 2018; Wang, 1992). In pregnant women, prevalences of 10% for *M. hominis* and 26.25% for *Ureaplasma* spp. were found. Among the pregnant, *Ureaplasma* spp. was the most frequently isolated, specially primigravidas and during the second gestational trimester (Castellano-González et al., 2007) while the recovery rate of *U. urealyticum* in girls with no history of sexual contact was significantly lower (Wang, 1992).

Table 1 Species of *Mycoplasma* spp. and *Ureaplasma* spp. with clinical interest.

Species	Location	Metabolism	Classification
<i>Mycoplasma pneumoniae</i>	Respiratory tract Rarely genital or other locations	Glucose	Pathogen
<i>M. salivarium</i>	Nasopharynx and oropharynx	Arginine	Commensal
<i>Mr. Oral</i>	Nasopharynx and oropharynx	Arginine	Commensal
<i>Mr. Oral</i>	Nasopharynx and oropharynx	Arginine	Commensal
<i>M. faucium</i>	Nasopharynx and oropharynx	Arginine	Commensal
<i>M. lipophilum</i>	Nasopharynx and oropharynx	Arginine	Commensal
<i>M. primatum</i>	Nasopharynx and oropharynx	Arginine	Commensal
<i>M. hominis</i>	Genitourinary tract, tissues, blood	Arginine	Pathogen
<i>M. genitalium</i>	Genitourinary tract, Respiratory tract rarely other locations	Glucose	Pathogen
<i>M. fermentans</i>	Genitourinary tract, blood, tissues, urine	Glucose, Arginine	Opportunistic
<i>M. spermatophilum</i>	Genitourinary tract	Arginine	
<i>M. pirum</i>	Rarely in peripheral blood (HIV)	Glucose, Arginine	Unknown
<i>M. penetrans</i>	Genitourinary tract, urine	Glucose, Arginine	Opportunistic
<i>Ureaplasma urealyticum</i>	Orofaringe and genitourinary tract	Urea	Pathogen
<i>U. parvum</i>	Orofaringe and genitourinary tract	Urea	Pathogen

Adapted from Acosta B, Codina M, Mata L, and Meseguer M (2011) Diagnóstico microbiológico de las infecciones por *Mycoplasma* spp. y *Ureaplasma* spp. <https://www.seimc.org/contenidos/documentoscience/procedimientosmicrobiologia/seimc-procedimientosmicrobiologia40.pdf>; Winn WC, Allen SD, Janda WM, Koneman EW, Procop G, Scheckenberger PC and Woods GL (2008) *Koneman Diagnóstico Microbiológico: Texto y Atlas en Color*. p. 1475.

Genital ureaplasmas (*U. urealyticum* and *U. parvum* *M. genitalium* and *M. hominis*) are natural inhabitants of male urethra (Gdoura et al., 2007). In males, prevalence of *U. urealyticum* are 15–25% while for *M. hominis* are prevalence are 4–13.3% (Andrade-Rocha, 2003; Choi et al., 2018; Veiga et al., 2019).

Among the species that can be found in oropharynx, *M. pneumoniae* is the only clearly related to disease. *M. pneumoniae* occurs endemically worldwide. Infections can be observed throughout the year but tend to be more common in summer and early fall. Epidemic peaks can be observed every 3–7 years. Outbreaks of *M. pneumoniae* infections have been reported within families, schools, institutions and military bases. *M. pneumoniae* infections can occur in all ages. However, *M. pneumoniae* is reported to be most frequent among school age children 5–15 years of age and adolescents and young adults (Ding et al., 2020; Sauteur et al., 2018; Waites et al., 2017). Epidemic peaks can be observed every 3–7 years. Outbreaks of *M. pneumoniae* infections have been reported within families, schools, institutions, and military bases (Sauteur et al., 2018).

Other oropharynx colonizing species have rarely been described as respiratory pathogens or in other locations (Ding et al., 1988; Edouard et al., 2016; Ketchersid et al., 2020) (Table 1).

Pathophysiology

Mycoplasma pneumoniae

Mycoplasma pneumoniae respiratory tract infections can range in severity from mild to life-threatening (Waites et al., 2017).

M. pneumoniae can induce both upper and lower respiratory infections and occurs both endemically and epidemically worldwide. Although tracheobronchitis is a more common clinical manifestation, pneumonia is the most clinically important illness associated with *M. pneumoniae* infections. *M. pneumoniae* may be responsible for about 4 to 8% of community-acquired bacterial pneumonias (CABP) during periods of endemicity (Waites et al., 2017).

Other investigations have assessed the role of *M. pneumoniae* in upper respiratory tract infections such acute pharyngitis (Esposito et al., 2004).

M. pneumoniae reinfections are quite common because natural immunity to microorganism is short-lived, which can lead to poor pathogen elimination and in cases resulting in a carrier state (Waites et al., 2017). Some studies from different localization reveal colonization percentages of more than 50% in asymptomatic children, although percentages vary greatly depending on the study.

M. pneumoniae is an obligate parasite. Adherence of *M. pneumoniae* to host cells is critical for virulence, as evidenced by the lack of virulence in strains deficient (88). Binding of *M. pneumoniae* to the host cell surfaces relies on proteins modified with sialic acid and sulfated glycolipids (Krivan et al., 1989). Cytoadherence and motility require an attachment organelle, a polar cellular projection about 290 nm in length that is continuous with the cell membrane. Transmembrane proteins P1, B (P90), C (P40), and P30 are most directly implicated in cytoadherence. The major adhesion is due to P1 adhesin. Antibodies against P1 block cytoadherence and a mutant lacking P1 is nonadherent and avirulent (Waites et al., 2017). Cytoadhesion protects mycoplasmas from mucociliary clearance transmembrane proteins P1, B (P90), C (P40), and P30 are most directly implicated in cytoadherence. Following cytoadherence, *M. pneumoniae* stimulates mast cells to produce IL-4 and activates and induces cytokine production by peripheral blood leukocytes, respiratory epithelial cells, and macrophages. The more vigorous the cell-mediated immune response and cytokine stimulation, more severe is the clinical illness and pulmonary injury (Furr and Taylor-Robinson, 1993).

Hydrogen peroxide is produced locally, which has a cytopathic effect on airway epithelium and cilia and is responsible for persistent cough (Kashyap and Sarkar, 2010; Waites et al., 2017).

Community-acquired respiratory distress syndrome (CARDS) is mediated by an exotoxin initially identified as a surfactant protein A (SP-A)-binding protein, CARDS toxin, with sequence homology with the S1 subunit of pertussis toxin that have ADP-ribosyltransferase activity. Antibody responses to CARDS toxin can be demonstrated in humans with *M. pneumoniae* infection (Kannan and Baseman, 2006).

Clinical presentation

The clinical presentation of *M. pneumoniae* respiratory disease is often similar to what is seen with other atypical pathogens, particularly *Chlamydia pneumoniae*, various respiratory viruses and bacteria (Deeks et al., 2005).

The most common manifestation is tracheobronchitis, with a cough that may either be dry or productive of mucoid or mucopurulent sputum. Many patients may have nonspecific symptoms resembling those of an upper respiratory infection, which may include headache, sore throat, coryza, and otitis media.

Chest auscultation may reveal coarse rales and rhonchi if disease is limited to tracheobronchitis and fine inspiratory rales and dullness at lung bases if pneumonia has developed.

Radiographically, *M. pneumoniae* infection may be indistinguishable from a viral lower respiratory infection, with patchy airspace consolidation and round glass opacities.

This disease often spreads slowly through families, with an incubation time of approximately 23 days. *Mycoplasma pneumoniae* is a primary pathogen of mucous membranes, while other non-pathogenic *Mycoplasma* species colonize the surface of the respiratory mucosa. It is transmitted from person to person by air but, due to its high sensitivity to changes in temperature and humidity. The index case is likely to be an older child, 5–14 years of age, and children under five are more likely to have milder disease. In one study, *M. pneumoniae* infection typically resulted in a prolonged cough that lasted 3–4 weeks. In older children and adolescents and an average of 54 days in adults (Foy, 1993).

M. pneumoniae pneumonia is typically mild and characterized by a persistent dry cough or self-limiting pneumonia, that resolves with no medication. However, respiratory failure and severe acute respiratory distress syndrome (ARDS) occur in 0.5–2% of all *M. pneumoniae* pneumonia cases and primarily affect young adults (Ding et al., 2020).

Uncommon fulminant and/or fatal cases of *M. pneumoniae* have been reported in healthy younger persons, as well as older persons with underlying diseases. Persons with severe illness may experience a hyperimmune response in the lung, they may also be unable to eradicate the organism from the lung, resulting in a prolonged infection which further stimulates the immune system (Waites et al., 2017).

Some authors have investigated the role that colonization by *M. pneumoniae* can play in chronic respiratory diseases such as asthma in both neonates and the pediatric population (Patel et al., 2011).

Extrapulmonary manifestations

Even though the humoral response to infection does not provide complete immunity to future infections, the importance of an intact humoral immune system takes on great importance. Patients with antibody deficiency can develop severe and prolonged respiratory illness and the risk of extrapulmonary also increases (Waites et al., 2017).

Central nervous system manifestations are the most frequent extra-pulmonary complications of *M. pneumoniae* infection and can at times be life threatening (Kashyap et al., 2008). Frequently, a manifest respiratory infection precedes the central nervous system symptoms. Involvement can occur in the brain, spinal cord, meninges, and peripheral nerves. Encephalitis, which occurs more commonly in children than in adults and may not have a respiratory component to the illness (Waites et al., 2017). Early-onset encephalitis is more likely to be PCR positive, indicating a direct effect of the organism, while late-onset encephalitis is usually PCR negative and associated with antiganglioside antibodies which may develop because of cross-reactivity with mycoplasmal glycolipids (Waites et al., 2017).

Nonspecific gastrointestinal symptoms commonly accompany mycoplasmal dermatological disorders, development of the phenomenon of “cold agglutinins” that can reach levels sufficient to trigger a brisk hemolytic anemia pericarditis, cardiac tamponade, myocarditis, myopericarditis (Kashyap and Sarkar, 2010; Waites et al., 2017).

Septic arthritis due to invasion of the joints mainly in persons with antibody deficiency or Hepatitis with severe liver dysfunction and pancreatitis has also been reported.

Other nonspecific manifestations can include conjunctivitis, iritis, and uveitis, which are presumed to have an immunological basis since the organism has not been detected in ocular tissues (Waites et al., 2017).

Other species of *Mycoplasmas* such as *M. orale* and *M. faucium*, commonly considered oropharyngeal commensal, have also been described as causing non-respiratory disease (Edouard et al., 2016; Ketchersid et al., 2020).

Genital mycoplasmas and ureaplasma

Urogenital diseases

Genital mycoplasma *M. genitalium* and *M. hominis* causes between 10% and 30% of genitourinary diseases (Beeton et al., 2019; Gdoura et al., 2007) mainly in non-gonococcal urethritis. The role of *Ureaplasma* spp. (*Ureaplasma urealyticum* and *Ureaplasma*

parvum) in nongonococcal urethritis and infertility among males still remains controversial, due to historically high rates of isolation of these bacteria from the urethra in healthy men, however, there is growing evidence to support that they can be considered true genitourinary pathogens especially in the male (Marovt et al., 2015).

Symptomatic patients and, if observed, those with a visible discharge should be assessed for the presence of urethritis. The discharge is mucopurulent and often sparse but may be cloudy or clear (Moi et al., 2015).

M. genitalium, has a strong association with acute, persistent UNG after treatment and recurrent, in both males and women. *M. genitalium* also has a significant association with balanitis and/or posthitis. *U. urealyticum*, has been related to UNG, *Ureaplasma* spp. it is also related to a small proportion of chronic prostatitis cases and as a rare cause of epididymitis. Symptomatic patients and, if observed, those with a visible discharge should be assessed for the presence of urethritis. The discharge is mucopurulent and often sparse but may be cloudy or clear (Moi et al., 2015).

Genital mycoplasmas and *Ureaplasma* have been linked to urinary tract infection in patients with chronic unexplained urinary tract symptoms. *Ureaplasma* urinary tract infection also has been evaluated primarily in pregnant women and their isolation in the first trimester of pregnancy has been linked to the development of preeclampsia in the third trimester. Some authors have obtained up to 48% of positive crops for mycoplasmas (predominantly *Ureaplasma* spp.) in women with chronic symptoms of urinary tract infection, once the most common etiological agents have been excluded. *Ureaplasma urease* induces the crystallization of struvite phosphate and calcium in urine, in vitro and animal models. In addition, these microorganisms have been isolated in renal stones of patients (Combaz and Kuhn, 2017).

Ureaplasma spp. and *M. hominis* participate in chronic reflux pyelonephritis with 7% and 9%, respectively, of isolations from urine obtained by suprapubic puncture (Combaz and Kuhn, 2017).

They have also been reported from renal stone and suppurative arthritis (Kokkayil and Dhawan, 2015).

In women, *M. genitalium* is significantly associated with cervicitis, although co-infections with other sexually transmitted infection agents are common. Also *M. hominis* and especially *M. genitalium* have been linked to the development of Inflammatory Pelvic Disease (PID) while *U. urealyticum* has also been found in PID and cases of miscarriage (Meseguer-Peinado et al., 2012).

Infertility

The fact that genital mycoplasmas are part of the urogenital microbiota calls into question its role in infertility (Gnanadurai and Fifer, 2020; Zhou et al., 2018). Some of these infections may be paucisymptomatic or asymptomatic, but acute infections such as chronic infections can compromise spermatogenesis (Solomon and Henkel, 2017). The prevalence of these microorganisms has been seen to be higher in samples from patients undergoing fertility treatments and that their detection in high count is related to lower sperm quality (Beeton et al., 2019; Díaz-García and Flores-Medina, 2013; Gdoura et al., 2007; Solomon and Henkel, 2017; Zhou et al., 2018). On the other hand, the presence of genital mycoplasmas with genital disease in women has also been linked so some authors recommend the systematic search of these microorganisms in infertile partner samples (Veiga et al., 2019).

Disease in pregnancy, childbirth and postpartum

Bacterial Vaginosis is a microbiological entity in which the normal vaginal microbiota is altered in its composition, with loss of the main components and predominance of other species such as *Mycoplasma* or *Ureaplasma* (Meseguer-Peinado et al., 2012). Genital mycoplasmas were isolated from gravid women at approximately the same recovery rate as in non-pregnant women; being *M. hominis* the most frequently isolated in non-pregnant women and *Ureaplasma* spp. in the pregnant group (Patel et al., 2011). The prevalence of bacterial colonization in women has been shown to correlate with number of sexual partners in previous months. Sex hormones have a profound influence on colonization, multiplication, and persistence of mycoplasmas/ureaplasmas in the genital tract (Furr and Taylor-Robinson, 1993; Taylor-Robinson, 2017).

The prevalence of bacterial colonization in women has been shown to correlate with number of Genital mycoplasmas are capable of hampering reproductive outcome by attaching to and penetrating the human sperm plasma membrane, which in turn affects male fertility, cause cervicitis, acute chorioamnionitis, preterm labor or preterm premature rupture of membranes, postpartum fever, and infection transmission to the newborn infant or (Feng et al., 2016; Goldenberg et al., 2008; Kwak et al., 2014; Latino et al., 2018; Solomon and Henkel, 2017; Suzuki et al., 2018). Colonization with *U. parvum* serovar three in early pregnancy is associated with preterm delivery at very and extremely low gestational age (Rittenschöber-Böhm et al., 2019).

The transmission of ureaplasmic infections from the mother to the fetus occurs in the uterus or during labor. They can cause ascending infection after rupture of membranes (Bartkeviciene et al., 2020). Membrane phospholipases A1, A2, and C of *Ureaplasma* spp. hydrolyze the phospholipids of the placenta, with release of arachydonic acid, and the consequent production of prostaglandins triggering childbirth. In addition to both *M. hominis* and *U. urealyticum*, they can produce active proteases against IgA which facilitates mucosal invasion. On the other hand, the presence of phospholipases alters the function of the pulmonary surfactant of the fetus, with the consequent risk of bronchopulmonary dysplasia in preterm newborns, because they increase lung inflammation and alter their normal development (Acosta et al., 2011a).

Respiratory distress syndrome (RDS), a major cause of morbidity and mortality in preterm infants, is caused by cardiopulmonary immaturity with a deficiency of surfactant in the alveolar space. RDS is often associated with patent ductus arteriosus (PDA), intraventricular hemorrhage and chronic lung diseases. *Ureaplasma urealyticum* and *Mycoplasma hominis* have been linked to the development of chronic lung disease or bronchopulmonary dysplasia and RDS (Cultrera et al., 2006; Goldenberg et al., 2008).

Diagnosis

Microbiological diagnosis of infections caused by mycoplasma and ureaplasma has long been limited by the fastidious growth of these microorganism in conventional culture media which could lead to an underdiagnosis. This situation has changed markedly in recent years thanks to advances in serological diagnostic methods and the application of nucleic acid amplification methods what has down drawn an increase in their detection and, consequently, in the appreciation of the clinical importance of these microorganisms (Acosta et al., 2011a).

Culture of human mycoplasmas is useful only for the isolation of pathogenic species with a reasonably satisfactory growth in specific media, such as *Ureaplasma* spp., *M. hominis* and *M. pneumoniae* but not for extremely annoying growth species, such as *M. genitalium*, *M. fermentans* and *M. penetrans*, etc.

Growth in artificial media these need a supply of sterols, fatty acids, cholesterol amino acids and other compounds. These media are generally based on a brain-heart infusion broth (BHI) with nutritional supplements and antibiotics to inhibit the accompanying microbiota, in addition to a metabolite (glucose or urea, depending on the species) and a pH indicator such as phenol red.

Currently there are commercial galleries with microwells containing lyophilized antimicrobials, usually in two or more concentrations corresponding to the cut-off points proposed for classification of the isolate as sensitive, intermediate, and resistant. The reading of the test is also based on the presence/absence of color change of the culture medium. Some of these teams also incorporate the growth of the organism providing an approximate colony count and differentiation between mycoplasma and ureaplasma (Acosta et al., 2011a).

Respiratory, genital samples or other locations such as CSF, pericardial fluid, synovial fluid, skin or tympanic vesicle fluid and blood or serum may be cultured, taking into account that they are collected in swabs, these should be calcium alginate, dacron or polyester with plastic or aluminum stem, since cotton and wood exert an inhibitory effect on the microorganism.

M. pneumoniae grows very slowly and culture are not widely available in clinical microbiology laboratories. Sensitivity is less than 50% compared to serology so microbiological diagnosis, in clinical practice, has generally been based on the demonstration of specific antibodies.

Immunoglobulin M (IgM) assays that are more sensitive than the complement fixation (CF) test ha, but the IgM response may be nonspecific 7 or absent, particularly in adults 8. Hybridization with DNA probes proposed as a rapid and specific procedure but lacks sensitivity (Wang et al., 2017).

Passive agglutination techniques use a support, such as latex or gelatin, for a mixture of *M. pneumoniae*-specific antigens can detect IgG and IgM, also allowing their quantification. They are techniques of very easy realization and considerable specificity, although, to achieve maximum sensitivity (66%) it is recommended to make the determination in two serial samples (Templeton et al., 2003) enzymeimmunoassay techniques (EIA) using purified proteins, synthetic peptides, mixture of raw antigens or purified glycolipids to the detection of IgG or IgM with different presentations like capture-μ techniques, microplates, in membrane support can be used. EIA tests appear very sensitive for the detection of specific antibodies. Presentations in membrane support allow qualitative determinations of IgM, very quickly with good sensitivities and specificities.

Detection of IgA is considered to be the best indicator of acute infection, without.

However, using reagents marketed, found 68.5% positivity for this immunoglobulin in blood donors (Csángó et al., 2004).

Serological tests have been developed for the diagnosis of genital *Mycoplasmas* or *Ureaplasma* spp. using highly immunogenic membrane proteins with high specificity. These diagnostic tests may be useful to help clarify the participation of these microorganisms in certain clinical entities but not for daily clinical practice and are only used in the field of research (Winn et al., 2008).

Molecular-based tests such as the PCR assay are becoming more widely used for diagnostics because they are more time-efficient and sensitive than culture because of their high sensibility, specificity and suitability for various types of samples, including vulvovaginal swabs, urethral exudate y and first-catch urine, both individually and in Multiplex PCR for the diagnosis of the most common sexually transmitted disease-producing pathogens (Carneiro et al., 2020; Hilmarisdóttir et al., 2020; Le Roy et al., 2012).

The genes used to detect these microorganisms are detailed in Table 2.

Table 2 Target for detection of Mycoplasma and Ureaplasma.

Species	Target gen
<i>Mycoplasma</i> spp.	16S RNAr
<i>M. genitalium</i>	Adhesina MgPa
<i>M. hominis</i>	Gap (glycolytic enzyme glirelandahide-3 phosphate dehydrogenase)
<i>Ureaplasma</i> spp.	16S ARNr
<i>Ureaplasma urealyticum</i>	ureB (Urease complex component)

Treatment

Since they do not have a cell wall, these microorganisms are intrinsically resistant to antimicrobials whose target is this, such as β -lactams. Mycoplasmas are generally sensitive to tetracyclines, macrolides, lincosamides, streptogramins, fluoroquinolones, aminoglycosides, chloramphenicol and linezolid. *M. pneumoniae* and *Ureaplasma* spp. They are intrinsically resistant to lincosamides and *M. hominis* to macrolides. The most used antimicrobials in the treatment of infections caused by these microorganisms are fluoroquinolones, macrolides and tetracyclines. Sensitivity levels against ciprofloxacin range from 20% to 50%, reaching 80% in some series, while against ofloxacin, moxifloxacin and levofloxacin sensitivity levels, they are generally higher than 50% for both ureaplasma and mycoplasma species. Sensitivity to tetracycline and doxycycline is generally high (above 80% in most series), being somewhat lower for macrolides, among which Azithromycin has lower resistance values.

PCR and sequencing techniques have detected mutations that confer resistance against different antimicrobial agents such as tetM present in the tetracycline-resistant isolate and a mutation within the parC or gyrA in the quinolone-resistant isolate, as well as mutations in the gene encoding for 23S rRNA gene, which confers resistance against macrolides (Orellana and Gómez-Lus, 2011; Choi et al., 2018; Lee and Yang, 2020; Leli et al., 2012; Piñeiro et al., 2019; Redelinguys et al., 2014; Valentine-king and Brown, 2017).

Glossary

BGMK Cell line from African green monkey kidney cells, commonly used for the isolation of *Chlamydia trachomatis* and Enterovirus.

HeLa Cell line from epithelial cell from human cervix adenocarcinoma.

Hep2 Cell line from epithelial human carcinoma.

HL Cell line from human promyeloblasts.

McCoy Cell line from fibroblast cell from mouse, commonly used for the isolation of *Chlamydia trachomatis*.

Nomenclature

CAP	Community acquired pneumonia
CDCs	Centers for Disease Control and prevention
ECOFFs	Epidemiological cut off values
EIAs	Enzyme immunoassay
HAP	Hospital acquired pneumonia or Nosocomial pneumonia
IC	Immunochromatographic
IFA	Indirect fluorescent antibody

IV	Intravenous
MALDI-TOF MS	Matrix-Assisted Laser Desorption Ionization Time of Flight Mass Spectrometry
mg	Milligram
MIC	Minimum inhibitory concentration
NAATs	Nucleic acid amplification techniques
PCR	Polymerase chain reaction
PO	Orally
spp.	Species
STDs	Sexually transmitted diseases
μm	Micrometer

Legionella

Taxonomy

The order Legionellales belongs to the phylum proteobacteria and class gammaproteobacteria. This order includes two families Coxiellaceae and Legionellaceae. The most representative species of those families, *Coxiella burnetii* and *Legionella pneumophila*, respectively; show similar growth characteristics and close homologies in virulence genes (Edelstein, 2019; Sauer et al., 2005; Segal et al., 2005).

Legionellaceae has a single genus, *Legionella*, with at least 59 different species, 3 subspecies and more than 70 serogroups (Boyd, 1995a; Brenner et al., 1980).

Some of the most commonly isolated in clinical specimens are (Mensa et al., 2016a):

Legionella anisa, *L. bozemanii*, *L. cardiaca*, *L. cincinnatiensis*, *L. dumoffii*, *L. feeleii*, *L. gormanii*, *L. hackeliae*, *L. jordanis*, *L. lansingensis*, *L. londiniensis*, *L. longbeachae*, *L. macaechernii*, *L. micdadei*, *L. nagasakiensis*, *L. oakridgensis*, *L. parisiensis*, *L. pneumophila*, *L. quinlivanii*, *L. sainthelensi*, *L. steelei*, *L. tucsonensis*, *L. wadsworthii*, *L. waltersii*.

The majority of species are considered pathogenic, even so *L. pneumophila*, *L. micdadei*, *L. longbeachae* and *L. dumoffii* are the most significant from a clinical point of view. *Legionella pneumophila* has 17 known serogroups, being serogroup 1 the most prevalent in human disease.

There are a number of *Legionella*-like bacteria, which only grow within free amoeba, known as “LLAPs” (*Legionella*-like amoeba pathogen) that have been reported to be involved in human disease usually as co-pathogen (Marrie et al., 2001; Newsome et al., 1998; Adeleke et al., 2001).

General characteristics

The family Legionellaceae includes a diverse group of mesophilic, obligate aerobic small gram-negative bacilli. Most of species are motile due to a single polar flagellum and possess fimbriae. The surface of its cell wall contains cellular branched-chain fatty acids and ubiquinones which is not common on gram negative bacteria.

Their size and shape varies from small rods to long filamentous bacilli depending on developing conditions. The intracellular bacteria from clinical specimens or environmental samples range between 0.3 and 0.4 μm in diameter and 2.0–3.0 μm in length. However those bacteria isolated in agar plates has shown up to 25 μm of length.

Legionella species (*Legionella* spp.) are asaccharolytic and nutritionally fastidious; their growth depends on L-cysteine and is enhanced by iron (Winn Jr, 1996). Temperatures from 35°C to 45 °C are optimum for Legionellaceae, although they can tolerate up to 55 °C; regarding pH they can only grow on a narrow range of pH 6.7–6.9.

The reservoir of *Legionella* organisms is usually fresh water. The species of this family have been isolated from rivers, lakes, wet soil, fountains, ponds, water supply systems, cooling towers, aerosol therapy equipments, mist humidifier as well as air-conditioned facilities, among others. *Legionella* attach to elements such as pipes, rubber, plastics and sediments. They multiply and survive inside amoebas and ciliated protozoa often found within microbial biofilms, this allows the bacteria to remain protected from external aggressions (e.g., chlorination procedures or extreme temperatures). *Legionella longbeachae* is found in wet soil, specially potting soil and compost, where it may parasite insects or worms (Edelstein, 2019; Boyd, 1995a; Currie and Beattie, 2015; Steele et al., 1990).

Inside the human body it is a facultative intracellular parasite of macrophages (lysosomes and endoplasmic reticulum) usually within the lungs of infected individuals (alveolar macrophages).

Epidemiology and transmission

The Legionnaire's disease and its causal agent were first distinguished from other atypical pneumonia in 1977, after an outbreak of unknown pneumonia developed in Philadelphia at the Pennsylvania State Legionnaires Convention, in July 1976. More than 200 individuals were infected and the mortality rate ascended to a 15%. (Edelstein, 2019). Although that outbreak in 1976 allowed identifying and classifying the agent; Legionellaceae have been isolated since 1940s and a previous outbreak of atypical pneumonia that took place in the summer of 1957 in Austin, Minnesota at a local meat packing plant has been ascribed to Legionnaire's disease bacteria in retrospective (Osterholm et al., 1983).

Mechanism of transmission is inhalation of contaminated aerosols. It is less common by aspiration of contaminated water or ice in susceptible hospital patients. A possible person-to-person transmission has been documented (Borges et al., 2016).

Legionnaire's disease distributes worldwide. The incidence is underestimated and varies depending on the level of diagnosis and reporting, as many countries lack of neither appropriate methods to identify the infection nor surveillance systems. In Europe, United States and Australia there are about 10–15 cases per million population per year. Of the reported cases 75–80% are over 50 years old and 60–70% are male. Other risk factors for community-acquired and travel-associated legionellosis include:

- Cigarette smoking (current or historical).
- Chronic heart and lung disease.
- Underlying illness such as diabetes, renal or hepatic failure.
- Immune system disorders due to disease or medication.
- Systemic malignancy.
- Exposure to a contaminate source (overnight travel as well as overnight stay in a healthcare facility, use of well water, recreational water, etc.).

Patients at particularly high risk of Legionnaires disease are those receiving high dose of glucocorticosteroids, solid organ transplant and those receiving antitumor necrosis factor therapy.

Death rate depends on the severity of the disease, the administration of the appropriate antibiotic as soon as possible, host factors as mentioned before, as well as the identification of the infection source. Patients with no underlying illness receiving the correct antimicrobial treatment can be cured in 95–99% of the cases; untreated disease has a mortality rate of 15%, for this group of patients, increasing to a 75% on several immunocompromised ones (Edelstein, 2019; Joly et al., 1986).

Community-acquired Legionnaire's disease is caused in 95–98% by *Legionella pneumophila* serogroup 1 where Pontiac subtype constitutes about 80–90% of clinical isolates. Other serogroups described less frequently are 6, 5, and 10 (Byrne et al., 2018; Visca et al., 1999; Chen et al., 2006; Zhang et al., 2014; Graham et al., 2020).

Nosocomial infection may be caused up to a 60% by other serotypes of *Legionella pneumophila* serogroup 1, as well as other serogroups of *Legionella pneumophila* and *Legionella* spp.

Pneumonia caused by *Legionella* occurs along the year with seasonal peaks of the disease during the warmer seasons due to the use of air-conditioning, water spray cooling systems, water pools and amusement water parks. About 60% of the reported cases from Europe and United States take place between June and October.

Pathogenesis

Legionella invades and grows within alveolar macrophages, mistaking them for their natural host and causing disease. Most of the known species of this family have been isolated in cases of pneumonia, sometimes being more than one type of legionella organisms involved in the same infection.

- Legionnaire's disease (community-acquired pneumonia and hospital-acquired pneumonia) shows an acute onset of lower respiratory illness with fever and/or cough. Additional symptoms are myalgia, shortness of breath, headache, malaise, chest discomfort, confusion, nausea, diarrhoea or abdominal pain. Pathogenesis is due to the replication of bacteria inside the alveolar macrophages. The incubation period ranges from 2 to 10 days, with a median of 4 days.
- Pontiac fever is an influenzae-like illness caused by *Legionella* spp. in humans. Symptoms include fever, chills, myalgia, malaise, headache, fatigue, nausea and/or vomiting. Pathogenesis is due to the inflammatory response to endotoxin. The incubation period vary from 24 to 72 h after exposure.
- Extra-pulmonary infections have been reported although it is extremely rare. They are due to hematogenous dissemination of the pathogen from a primary focus (Table 1). Those include endocarditis, myocarditis, pericarditis, pancreatitis, peritonitis, skin and soft tissue infections as well as arthritis among others. In neonates can cause bacteremia and/or pneumonia.

Table 1 Shows a summary of infections caused by some *Legionella* spp.

	Respiratory infection	Extra-pulmonary infection
<i>L. anisa</i>	Pontiac fever Pneumonia Empyema	Osteomyelitis
<i>L. bozemanii</i>	Pneumonia (immunocompromised patients) Lung abscess	Arthritis Soft tissue infection
<i>L. cardiaca</i>		Endocarditis
<i>L. cincinnatiensis</i>	Pneumonia	Recurrent soft tissue abscess
<i>L. dumoffii</i>	Pneumonia Lung abscess	Arthritis Prosthetic valve endocarditis
<i>L. feeleyi</i>	Pontiac fever Pneumonia	Cellulitis
<i>L. hackeliae</i>	Pneumonia	Multi-organ failure on splenectomy patients
<i>L. jordanis</i>	Chronic respiratory disease	
<i>L. londiniensis</i>	Pneumonia on immunocompromised patients	
<i>L. longbeachae</i>	Pneumonia (30% of Legionnaires disease in Australia and New Zealand)	Endocarditis Eye infections Skin infections on immunocompromised patients Soft tissue infection
<i>L. macaecheirii</i>	Pneumonia Lung abscess	
<i>L. micdadei</i>	Pneumonia (immunocompromised patients) Lung abscess	Brain abscess Prosthetic joint infection Prosthetic valve endocarditis Severe cellulitis

Methods of diagnostic

Radiologic features

Chest X-ray features on Legionnaires disease are non-specific but may aid in diagnosis and management of the patient with *Legionella* infection. Findings include a mid-to-lower zone predominance of patchy consolidation; infiltrates frequently progress despite initiation of appropriate antibiotic therapy. Pleural effusion is common and occasionally appears in absence of lung infiltrates. Peripheral densities and cavitations are common in immunocompromised patients (Muder et al., 1987; Kim et al., 2007).

Culture

Clinical specimen culture is the gold standard method for *Legionella* identification; it allows detecting every specie and serogroup of *Legionella*. Clinical and environmental isolates may be compared by culture on epidemiologic studies.

Sputum, lower respiratory tract secretions, sterile fluids and tissues from any suspected location of infection are acceptable for culture. A better yield of bacteria from the specimen can be achieved by dilution (1:10) in tryptic soy broth or distilled water for sputum and respiratory secretions. Tissues (1 g, ideally) should be grounded with 1 mL of broth, except from spleen which requires a 1:10 dilution. Sterile fluids as well as blood sub-cultured from blood culture bottles don't need to be diluted before plating, although centrifugation may be useful to concentrate bacteria in pleural fluid for example (Edelstein, 2019).

The buffered charcoal yeast extract medium with α -ketoglutaric acid (BCYE α) yields optimal recovery of Legionellaceae from clinical specimens and environmental samples after a short incubation period. Selective media are supplemented with antimicrobial agents to inhibit the growth of yeast, fungal and other bacteria. To optimize the isolation of Legionellaceae it is necessary to use at least a non-selective and a selective media (Table 2).

Plates should be incubated at 35 °C–37 °C in humidified air. A CO₂ supplementation (2–5%) enhance the growth of some *Legionella* spp. without affecting *L. pneumophila*, however this is not used by clinical laboratories due to the low prevalence of those capnophilic species in human infection. Incubation should last for at least 14 days; cultures should be inspected on days 1, 5 and 14 of incubation. *Legionella* spp. never grows from clinical specimens after 24 h of incubation.

Size and morphology of the colonies vary with time. Diameter may range from 0.5 mm after 3 days of incubation to 7 mm on day 5. Colonies are gray, glistening, convex and circular with an entire edge, although the aspect would change along the course of incubation. Several species exhibit a blue-white auto-fluorescence, and most species produce a diffusible brown pigment on tyrosine-containing agar.

To identify presumptive *Legionella* spp. colonies from other gram negative bacteria, a sub-culture on BCYE α and BCYE α -L media can be done; Legionellaceae won't grow on BCYE α -L medium as require L-cysteine to do so.

Biosafety level 2 precautions should be used for *Legionella* spp. cultures

Table 2 Description of some of the most commonly used media.

Medium	Selective agent	Selectivity	Main use
BCYE α	None	None	Isolation and culture maintenance
BCYE α -L	None	<i>Legionella</i> spp. doesn't grow on this medium	Organism identification
BMPA	Cefamandole, Polymyxin B and Anisomycin	Respiratory and intestinal microbiota, yeasts and some molds	Clinical and environmental
GVPC	Glycine, Vancomycin, Polymyxin B and Cycloheximide	Respiratory and intestinal microbiota yeasts and molds	Clinical specimens and environmental water samples
GVPN	Glycine, Vancomycin, Polymyxin B and Natamycin	Respiratory and intestinal microbiota yeasts and molds	Environmental water and related materials
MWY	Glycine, Polymyxin B, Anisomycin and Vancomycin	Respiratory and intestinal microbiota, some environmental bacteria, yeasts and some molds	Environmental samples

Legionellaceae are faintly staining Gram-negative filamentous bacilli, this morphology is completely different from the one found in clinical specimens (coccobacilli). Legionellaceae are relatively inert biochemically, some key reactions for identification may include: catalase positive (some may show a weak reaction), oxidase-variable, urease-negative and nitrates negative.

Alternative identification methods include MALDI-TOF MS (matrix-assisted laser desorption ionization time of flight mass spectrometry) that is a rapid and cost effective method, available in most routine laboratories now a days, or DNA sequence-based methods used in public health or reference laboratories to identify species and serogroup level for outbreaks investigation or scientific projects.

Antigen detection

Antigen detection test is performed in urine samples. The assay detects *Legionella pneumophila* serogroup 1 and in particular the Pontiac/mab2/Mab3-1 monoclonal subtype. Several assays are available based on immunochromatographic (IC) card or micro-tube enzyme immunoassay. The IC card is an easy, quick and robust assay but its sensitivity can be up to a 40% lower than the micro-tube assay one.

The antigen detection may be negative on the first day of illness although patients with a severe disease can have a positive test since the onset of symptoms. Following a negative result with compatible symptoms a second sample should be tested 48–72 h after the onset of clinical manifestations.

The detection of the antigen in urine can be prolonged for weeks or months after the patient has completely healed; this is related to the clearance of the pathogen and doesn't evidence a treatment failure.

The sensitivity of the antigen detection varies from 60% to 100% depending on the assay performed, clinical severity and the management of the specimen, sensitivity may decrease if the specimen has been frozen (–20 °C to –80 °C) for several months.

Some studies have shown that the use of ultra-filtration to concentrate the urine can increase sensitivity (Blanco et al., 2004; Domínguez et al., 1998). The specificity of the assays ranges from 95% to 99.9%. False-positive results are usually due to an excess of urinary sediment, rheumatoid arthritis-like factors or melting of frozen urine samples.

Urine antigen detection for diagnosis of community acquired Legionnaires disease in areas where *L. pneumophila* serogroup 1 is more prevalent is highly recommended even so using urine as a single specimen for diagnosis is not recommended.

This method doesn't facilitate identification of linkages between clinical isolates and potential environmental exposures.

Molecular diagnosis

Nucleic-acid amplification techniques (NAATs) for detection of *Legionella* spp. can be performed on lower respiratory tract secretions, sterile fluids, tissues, serum and urine. Sputum digestion is recommended as it helps to eliminate PCR (polymerase chain reaction) inhibitors and produce better results (Avni et al., 2016; Peci et al., 2016; Benitez and Winchell, 2014; Brunel and Charpentier, 2016; Mérault et al., 2011).

The most commonly used primers are:

- 16S rRNA for detection of *Legionella* spp.
- mip (macrophage infectivity protein gene) for detection of *L. pneumophila*.
- ssrA codes for tm-RNA in *L. pneumophila*.
- wzm is part of the lipopolysaccharide (LPS) gene cluster in *L. pneumophila* serogroup 1.

Multiplex assays are usually preferred as in nosocomial infections and immunocompromised patients with Legionnaire's disease; as it is important to test for both *L. pneumophila* and *Legionella* spp. This is also relevant in areas where *L. longbeachae* infection is more prevalent.

Sensitivity of PCR ranges from 80% to 100% in most clinical specimens. This percentage drops to 30% to 50% when the technique is performed on serum or urine specimens. Regarding specificity the value ranges from 95% to 99.9% for all sample types. False positives may be due to contamination of the nuclease-free water and extraction columns in the production process.

Although assays vary depending on the laboratory, PCR is a rapid, sensitive technique that allows identifying different species of *Legionella* from a wide range of clinical specimen.

Serology

Serological diagnosis by indirect fluorescent antibody (IFA) requires a rise in titer of fourfold or $\geq 1:128$ (seroconversion) in paired sera to be considered diagnostic of *L. pneumophila* infection. Approximately 5–10% of the population has titer $1:\geq 256$; therefore single acute phase antibody can't discriminate between Legionnaires disease and other causes of CAP (community-acquired pneumonia).

The presence of IgM in serum should not be used as evidence of acute-phase considering titers of IgM can last up to a year after infection. Total immunoglobulin determination is preferred to avoid misdetection of patients developing only one type of Ig (M, G or A) responses.

Paired serology is recommended and should be performed on a serum sample obtained at acute stage of the disease up to 2 weeks after the onset of symptoms and another one collected 3–6 weeks later. The first sample should be frozen (-20°C) whilst the serum from the convalescent-phase is collected (Yabuuchi et al., 1997; Zimmerman et al., 1982).

Microscopy

Microscopy techniques have the lowest sensitivity and specificity values of all the available tests for Legionnaires disease diagnosis.

- Direct fluorescent antibody (DFA) stain is the most sensitive and specific microscopic method. It detects *L. pneumophila* from tissues and sputum but requires exacting staining methods as well as an experienced microscopist to achieve a good level of identification.
- Acid-fast stain is useful on some *Legionella* spp. especially for *L. micdadei*. Fresh specimens and formalin-fixed tissues can be used. Morphology: small coco-bacilli.
- Silver stain can be used to observe the bacteria in embedded tissues; however this technique produces many artifacts that make difficult identifying the bacteria.
- Gram-stain is not recommended from the clinical specimen due to its difficulty and low sensitivity.

Several studies have been published comparing sensitivity between the different available tests to identify *Legionella* from clinical specimens. The results vary widely depending on the specimen collected, laboratory performance of the test, commercial kit used, patient's condition and severity of the disease, among other test-related factors. Table 3 shows a general resume of sensitivity and specificity of the most commonly used techniques provided by the CDC.

Every available identification method for *Legionella* spp. in clinical specimens has an inherent weakness, therefore more than one test should be performed and ideally more than one specimen collected. For patients with suspected CAP caused by *Legionella* spp. a sample of urine and sputum should be requested for antigen detection and culture, respectively. In case of nosocomial infection or immunocompromised patient with suspected Legionnaire's disease, culture and PCR of the appropriate specimen may be essential for diagnosis. Serologic diagnosis is recommended for epidemiologic studies.

Antimicrobial susceptibilities and treatment

Antimicrobial susceptibility testing is difficult to perform due to *Legionella* fastidious growth requirements; also the complex broth and agar media inactivate many drugs. In addition to this, the correlation between in vitro results and clinical outcome is uncertain; this is because the intracellular location of the bacteria cannot be accessed by some antimicrobials such as β -lactamics or aminoglycosides. Some *Legionella* spp. resides in sub-cellular compartments and may have a different respond to the treatment.

Antimicrobial susceptibility testing

There is no gold standard for antimicrobial susceptibility testing of *L. pneumophila*. The use of media containing charcoal result in elevated MICs for most relevant agents, however this supplementation may be necessary to achieve adequate growth.

Antimicrobial susceptibility testing should be used for detecting resistance mechanisms, although there is no enough data available to establish epidemiological cut off values (ECOFFs). There are published MIC distributions available (Zimmerman et al., 1982) that give an indication of susceptibility for wild type isolates using micro-tube dilution gradient test on BCYE α broth. E-test is not useful for susceptibility in clinical testing.

Table 3 Sensitivity and specificity of recommended diagnostic techniques for detection of *Legionella* spp.

Test	Sensitivity (%)	Specificity (%)
Culture	20–80	100
Antigen detection	60–100	99.9
Polymerase chain reaction (PCR)	95–99	99.9
Direct fluorescent antibody (DFA) stain	25–75	95
Paired serology	80–90	99

Antimicrobial resistance

Acquired antimicrobial resistance in *L. pneumophila* is extremely rare. However, a clinical isolate resistant to ciprofloxacin due to a single point mutation in the *gyrA* gene, has been reported and further fluoroquinolone resistant strains have been isolated from patients. Even so the clinical implications of resistance are uncertain (Edelstein, 2019).

Treatment

The antimicrobial agents successfully used for the treatment of Legionnaire's disease are macrolides, quinolones and tetracyclines.

Pontiac Fever is a self-limited illness; patients usually recover within a week, nevertheless supportive care should be used to relieve symptoms.

To prescribe the correct treatment it is necessary to consult local guidelines. The following treatment regimen (Mensa et al., 2016a) shows some of the most recommended antimicrobial agents and doses, but they must change depending on local guidelines.

Mild to moderate pneumonia is usually treated with Azithromycin 500 mg every 24 h p.o. (orally) during 3–5 days or Clarithromycin 500 mg every 12 h p.o. for 10 days.

In severe Legionnaire's disease including immunocompromised patients:

- Fluoroquinolones: Levofloxacin 500 mg every 12–24 h IV (intravenous) or Ciprofloxacin 400 mg every 8–12 h IV during 10–14 days.
- Azithromycin 500 mg every 24 h IV for 5–10 days.
- Association of Levofloxacin and Azithromycin.

Alternative treatment:

- Doxycycline 100 mg every 12 h IV or p.o.
- Co-trimoxazole (trimethoprim-sulfamethoxazole 160/800 mg) every 8–12 h IV or p.o.
- Association of Azithromycin with Rifampicin.

Chlamydia and Chlamydophila

Taxonomy

The family Chlamydiaceae (order Chlamydiales, phylum Chlamydiae) are important pathogens found throughout the animal kingdom. Although two genera, *Chlamydia* and *Chlamydophila*, were proposed and discussed for decades, recent studies have rejected the existence of *Chlamydophila* (Sachse et al., 2015).

From the diverse number of *Chlamydia* spp. found in nature only five have been recognized as pathogenic for humans (Wolff et al., 2018; Mensa et al., 2016b):

Chlamydia trachomatis, *Chlamydia pneumoniae*, *Chlamydia psittaci*, *Chlamydia abortus* and *Chlamydia felis*.

C. trachomatis is the most prevalent agent in human infection of the genus. It is divided into 15 serovar (A, B, Ba, C-K, and L1-L3) based on analysis of the MOMP (major outer membrane protein).

General characteristics

They are a small obligate intracellular gram-negative bacterium, their size ranges from 0.2 to 1.0 μm .

Chlamydiae cell wall possesses an outer membrane characteristic of that in gram-negative bacteria, but the lack of peptidoglycan distinguishes them from similar intracellular pathogen like Rickettsia.

Through its growth cycle Chlamydiae alternates between two forms (Marrazzo and Suchland, 2014):

- The elementary body (EB) which is extracellular and infectious, but metabolically inactive.
- The reticulate body (RB) which is the intracellular non-infectious form. This is metabolically active and the replicative form (Fig. 1).

Stages of Chlamydiae developmental cycle:

1. The elementary body binds a host cell surface receptor using a specific ligand. This activate a mechanism of endocytosis where the plasma membrane zipper around the bacteria (Cossart and Helenius, 2014).
2. Inside the host cell the bacteria resides in a vacuole (phagosome) and survives by inhibiting lysosome fusion.
3. The elementary body transforms to reticulate body.
4. The reticulate body multiplies by binary fission. Along this phase the phagosome enlarges forming the inclusion body.
5. Reticulate bodies differentiate back into elementary bodies.
6. The inclusion body enlarges more, containing both forms of the bacteria.
7. The elementary bodies are released by lysis or extrusion process, at this stage they are ready to attach the surface of adjacent host cells and initiate new cycles of infection.

Fig. 1 Chlamydia developmental cycle.

Epidemiology and pathogenesis

Chlamydia trachomatis

Chlamydia trachomatis eye infection

- Trachoma is a chronic ocular disease caused by repeated infections of the conjunctiva and cornea.

It is endemic in many areas of Africa, Asia, Australia, Central and South America and the Middle East. Worldwide this disease affects 500 million people and up to 9 million are reported to be blind from this condition.

The agent spreads by direct contact, contaminated fingers, facecloths, clothing, bed linen, pillows etc. due to infective discharges. The incubation period ranges from 1 to 3 weeks.

Chronic conjunctivitis develops follicles that may necrotize and cause scarring. Over the years the contraction of the scars can turn in the lids leading the abrasion of the cornea by eyelashes. Blindness could be due to conjunctival scarring or secondary bacterial infections (Boyd, 1995b).

- Inclusion conjunctivitis refers to an ocular Chlamydia infection that doesn't progress to blindness. It is usually a self-limited disease; however scarring has been reported in infants without a prompt treatment.
- Ophthalmia neonatorum is the ocular infection of the infant who gets exposed to the pathogen during passage through the infected birth canal. This can be caused as well by *Neisseria gonorrhoeae*. Around a 20% of infants exposed to infected mothers will develop inclusion conjunctivitis and around 15% will develop neonatal pneumonia.

Chlamydia trachomatis genital infection

- Urethritis, cervicitis and proctitis.
- Lymphogranuloma venereum (LGV) is a sexually transmitted disease caused by L1, L2, and L3 serovars of *Chlamydia trachomatis*. Three stages of the disease have been described. Initially the infection may be undetected, in this stage a painless papule or ulceration appears. On a secondary stage unilateral or bilateral lymphadenopathies known as buboes, appear along inguinal and/or femoral areas. On the third stage fibrotic lesions affect the genital and anal area. The incubation period takes around 1–4 weeks.

Asymptomatic infection is common among men and women, this is the reason why CDCs (Centers for Disease Control and prevention) recommend annual screening test on population at increased risk. Having multiple Chlamydia infections can develop serious reproductive health complications in women, including pelvic inflammatory disease and ectopic pregnancy. In men the complication of urethritis progress to severe epididymitis. Women and men should be retested about 3 months after the treatment of an initial infection.

LGV in men that have sex with other men (MSM) is associated with a high rate of co-infection with gonorrhoea, syphilis, herpes simplex virus, hepatitis C virus, and/or HIV. When LGV is suspected, diagnostic tests for other potentially coexisting STDs (sexually transmitted diseases) must be performed (Schachter and Chernesky, 2019; Ceovic and Gulin, 2015).

Chlamydia trachomatis is the world's most common sexually transmitted bacterial pathogen, leading the cause of non-gonococcal urethritis. The number of cases per population is underestimated due to asymptomatic infections, availability of diagnostic tests and lack of universal surveillance protocols. Most recent outbreaks of LGV in Europe and EEUU were caused by L2b affecting HIV men who have sex with men (MSM).

Confirmed cases of *Chlamydia trachomatis* infection should be notified to the reference center of disease control to monitor epidemiology of the disease and activate prevention strategies.

Chlamydia (Chlamydophila) pneumonia

This specie is a common etiologic agent of upper and lower respiratory tract infection. It is one of the pathogens of CAP. Clinical symptoms are similar those found in respiratory infections caused by other pathogens.

The pathogen is transmitted via respiratory droplets and has a long incubation period that may vary from 3 to 4 weeks after exposure. It has also been isolated from some animals like horses, koalas and snakes.

Outbreaks are usually reported from crowded communities like schools, military barracks, nursing homes, prisons or student residences among others. Seroprevalence in adult population reaches around 50–70%, but the real prevalence of this agent is unknown as there is no national reporting or surveillance of *Chlamydia pneumophila* infections (Mensa et al., 2016b; Schachter and Chernesky, 2019).

Chlamydia (Chlamydophila) psittaci

A pandemic of human psittacosis allowed identifying *C. psittaci* for the first time. The spread of the disease was due to infected parrots and other related birds that were exported worldwide from South America between 1929 and 1930.

C. psittaci is a pathogen of birds; in contact with humans it causes a wide range of clinical conditions from asymptomatic infection to fatal pneumonia and systemic infections. The incubation period is 5–14 days. Symptomatic infections usually present with an abrupt onset of fever and chills, headache, myalgia and non-productive cough. The mortality on patients receiving the appropriate treatment is less than 1%.

Psittacosis is classified as category B bioterrorism disease

The bacteria spread by feces and respiratory secretions from infected birds. Human transmission occurs by inhalation of dust and droppings, very rarely from bites or beak-to-mouth contact. Population at higher risk of exposure includes employees of poultry-processing plants, farmers, workers in avian quarantine stations, zoos or pet shops, as well as veterinarian and laboratory staff (CDC).

Chlamydia (Chlamydophila) abortus and Chlamydia (Chlamydophila) felis

These two species of Chlamydia affect mainly mammals but have been proven to cause disease in humans (Mensa et al., 2016b; Schachter and Chernesky, 2019).

- *Chlamydia abortus* is an important cause of abortion in goats and sheep, although cases of abortion have been reported in women. It is considered an occupational infection with a very low prevalence.
- *Chlamydia felis* can cause conjunctivitis in humans

Diagnosis

There are potential risks for laboratory-acquired infections with *Chlamydia* spp.; LGV biovar of *C. trachomatis* and *C. psittaci* are considered a Biosafety level 3 (BSL 3) organisms. The rest of human pathogen species of Chlamydia are considered BSL 2.

The diagnosis of Chlamydia species is usually performed by NAATs as is the most sensitive and easy diagnostic test available; it provides rapid detection and is useful on strain typing. But also antigen detection, culture and serology are useful methods (Schachter and Chernesky, 2019).

Molecular detection

For detection of *C. trachomatis* the PCR can be performed on first-catch urine samples and urethral swabs from men and vaginal or endocervical swabs from women. Rectal and posterior oropharynx swabs can be collected when infection is suspected on either site. Most of the commercially available PCR tests are duplex assays for simultaneous detection of *Chlamydia trachomatis* and *Neisseria gonorrhoeae*, as they are the most prevalent bacteria causing STDs.

For detection of *Chlamydia pneumoniae* and *Chlamydia psittaci* respiratory specimens (sputum, respiratory secretions, nasopharynx and oropharynx swabs) can be processed (Zimmerman et al., 1982).

Antigen detection

The appropriate specimens for these techniques include exudates from conjunctiva on *C. trachomatis* infection; respiratory secretions on *C. pneumoniae* and impression smear of liver and spleen the avian source, for the identification of *C. psittaci*.

- Giemsa stain may be used to detect inclusions as diagnose of conjunctivitis in newborns but is not sensitive for adult conjunctivitis or genital infection. This stain is also used to detect *C. psittaci* from specimens obtained from avian sources of human infection.
- DFA is useful as a rapid diagnosis of inclusion conjunctivitis on infants and probably in adults.

Serology

Serology methods show low specificity and sensitivity rates; even so it may be useful as a complement in the diagnosis of LGV, pneumonia infection on infants, human psittacosis and infections of *C. pneumoniae*. It is a useful tool in clinical epidemiologic studies and research.

The most used techniques are:

- Microimmunofluorescence for detection of specie and serovar specific antibody response as well as the Ig (immunoglobulin) class.
- Enzyme immunoassay (EIAs) as a good technique on epidemiologic studies.

Cell culture

This method is performed at specialized laboratories. Usually the culture needs a transport medium containing antibiotics to prevent other bacterial and fungal contamination. The clinical specimen should be introduced directly in the Chlamydia-specific transport medium.

For isolation of the bacteria the goal is to collect infected cells; for genital infection urethral swabs from men and endocervical swabs are recommended, in case of conjunctival infection the sample must be direct scrapings collected with spatula, but samples obtained by swabs are also acceptable. Tissue samples can be cultured as well. For the isolation of *C. pneumoniae* is indicated to collect respiratory secretions, sputum or throat washes. In the case of *C. psittaci* when avian species are suspected to be the source of human infection the specimens should be collected from liver, spleen or serofibrinous exudates coating those organs.

The inoculated cells (Table 4) may be incubated at $35 \pm 2^\circ\text{C}$ (35°C are optimal for *C. trachomatis*, but 37°C are preferred for *C. psittaci*) in an environment of 5% CO_2 for 48 to 72 h. After this period mono-layers are fixed with methanol and stained with DFA reagents to detect inclusions of the bacteria.

Treatment

Human infections caused by Chlamydia are usually treated with macrolides or tetracyclines; fluoroquinolones are prescribed as alternative. Treatment failures have been reported but the recommendation is to treat again the patient as there is no evidence of antibiotic resistance.

Antimicrobial susceptibility tests are not routinely performed, but there are published protocols (Schachter and Chernesky, 2019). MIC is defined in this case as the level of antibiotic that reduces inclusion counts by 50% (Table 5).

In addition to the treatment of sexually transmitted infections, patients should abstain from sexual activity for 7 days after starting the antibiotic treatment or until this has finished in longer courses, to prevent the spread to sexual partners.

Regarding Trachoma the World Health Organization has targeted it for elimination through a public health strategy known as S.A.F.E.

- Surgery to correct the advanced, blinding stage of the disease.
- Antibiotics to treat active infection.
- Facial cleanliness.
- Environmental improvements in the areas of water and sanitation to reduce disease transmission (Table 6).

Table 4 Shows the most common cell line used for Chlamydia culture.

Chlamydia spp.	Cell line
<i>C. trachomatis</i>	McCoy
	HeLa
	BGM
<i>C. pneumoniae</i>	HL
	Hep2

Table 5 Shows some of the recommended antibiotic regimes for *C. trachomatis*, although local guidelines or up to date recommendations from CDCs or WHO should be consult for an adequate treatment (Mensa et al., 2016b).

	Recommended	Alternative
Lymphogranuloma venereum	• Doxycycline 100 mg p.o. twice daily or 200 mg p.o. once daily for 2–3 weeks or • Azithromycin 1 g p.o. per week for 3 weeks Buboos should be drained or surgically removed Pregnant and lactating women should be treated with Erythromycin or Azithromycin	• Erythromycin 500 mg p.o. every 6 h or • Levofloxacin 500 mg p.o. daily for 21 days
Urethritis, Cervicitis and Trachoma	• Doxycycline 100 mg p.o. twice daily or 200 mg p.o. once daily for 7 days or • Azithromycin 1 g p.o. single dose	• Erythromycin 500 mg p.o. every 6 h or • Levofloxacin 500 mg p.o. daily for 7 days
Eye infection	• Azithromycin eye drops for 3 days. An oral treatment with tetracycline may be used in addition to the eye drops	

Table 6 Shows the recommended antibiotics for *Chlamydia abortus*, *pneumoniae* and *psittaci*.

	Recommended	Alternative
<i>Chlamydia abortus</i>	Doxycycline	
<i>Chlamydia pneumoniae</i>	Doxycycline 2–3 weeks or Azithromycin 3–5 days	Clarithromycin or Levofloxacin 2–3 weeks
<i>Chlamydia psittaci</i>	Doxycycline 10–14 days	Macrolides, Fluoroquinolones or chloramphenicol

Introduction

Ehrlichia and *Anaplasma* are a group of gram-negative bacteria, belonging to the order Rickettsiales and family Anaplasmataceae (Sneath et al., 1986). The Anaplasmataceae family is composed of five genera: *Ehrlichia*, *Anaplasma*, *Neoehrlichia*, *Wolbachia*, and *Neorickettsia* (Pruneau et al., 2014). These genera can be classified according to their transmission mechanism. The genera *Ehrlichia*, *Anaplasma*, and *Neoehrlichia* are transmitted by ticks, while the genera *Neorickettsia* and *Wolbachia* have different transmission mechanisms that do not require ticks (Pruneau et al., 2014).

Within the *Anaplasmataceae* family we find species that affect a wide multitude of hosts such as horses, cows, goats, etc., therefore having importance in the veterinary field (Dantas-Torres et al., 2018; Sato et al., 2020). The genera *Ehrlichia* and *Anaplasma* include species that can cause disease in humans. The main species are *Ehrlichia chaffeensis* y *Anaplasma phagocytophilum* and, to a lesser extent, the species *Ehrlichia ewingii* and *Ehrlichia muris euclairensis* (Dumler, 2005).

Ehrlichiosis, previously known as human monocytic ehrlichiosis (HME), is caused by *E. chaffeensis*, *E. ewingii*, and *E. muris euclairensis*. In 2008, ehrlichiosis were classified into four categories (Centers for Disease Control and Prevention, National Center for Emerging and Zoonotic Infectious Diseases (NCEZID), 2019a): (i) infection caused by *E. chaffeensis*, (ii) infection caused by *E. ewingii*, (iii) infection caused by *A. phagocytophilum*, and (iv) indeterminate ehrlichiosis/anaplasmosis. *E. muris euclairensis* infections are recently discovered and therefore are included in the indeterminate ehrlichiosis/anaplasmosis (Centers for Disease Control and Prevention, National Center for Emerging and Zoonotic Infectious Diseases (NCEZID), 2019a). These four categories also include anaplasmosis, previously known as human granulocytic anaplasmosis (HGA), which is caused by *A. phagocytophilum* (Bakken and Dumler, 2015).

The genus *Ehrlichia* and *Anaplasma* are obligate intracellular bacteria, which live inside modified vacuoles of monocytes and granulocytes (Zhang et al., 2007; Troese et al., 2011). They replicate inside the vacuoles and within a few days intracellular inclusions known as morulae can be observed (Zhang et al., 2007). In morulae we can find replicative forms that are not very infective and non-replicative forms that are highly infective (Zhang et al., 2007). They have a very simple cell wall, surface proteins to bind to the target cell and a type IV secretion system that they use to introduce their proteins inside the host cell and modify it: prevents the fusion of lysosomes, modifies the cytoskeleton and alters gene expression (Zhu et al., 2011; Rennoll-Bankert et al., 2015).

They have an aerobic metabolism. They cannot perform glycolysis but can use simpler substrates like glyceraldehyde-3-phosphate and phosphoenolpyruvate for the synthesis of other compounds. They use only proline and glutamine as a carbon source, having to be most of the amino acids exported from the host cell (Dunning Hotopp et al., 2006).

As they are obligate intracellular species, they cannot be grown in cell-free medium. *E. chaffeensis* can be cultured using monocyte and macrophage cell lines of canine, murine, primate, and human origin (Chen et al., 1995). *A. phagocytophilum* can be cultured in vitro using human myeloid leukemia cell lines (Troese et al., 2009). All species can be grown in tick embryonic cell lines.

Transmission

The transmission mechanisms for *Ehrlichia* and *Anaplasma* are the same, showing differences in the vector species. The main route of transmission is through an infected tick bite. *E. chaffeensis* and *E. ewingii* are transmitted by the lone star tick (*Amblyomma americanum*). *E. muris euclairensis* is transmitted by the black-legged tick (*Ixodes scapularis*) (Centers for Disease Control and

Prevention, National Center for Emerging and Zoonotic Infectious Diseases (NCEZID), 2019a). In the case of *A. phagocytophilum*, we found two vectors: *I. scapularis* in the northwestern and midwestern United States and *Ixodes pacificus* along the west coast (Centers for Disease Control and Prevention, National Center for Emerging and Zoonotic Infectious Diseases (NCEZID), 2019b).

Transmission by blood transfusion or transplantation is rare, but even fatal infections have been reported (Annen et al., 2012; Alhumaidan et al., 2013; Regan et al., 2013; Sachdev et al., 2014; Goel et al., 2018). *E. chaffeensis* and *A. phagocytophilum* can be isolated from blood anticoagulated with EDTA and stored at 4 ° C after 11 and 18 days, respectively (Kalantarpour et al., 2000; McKechnie et al., 2000).

The reservoir for *E. chaffeensis* is the white-tailed deer (*Odocoileus virginianus*) (Centers for Disease Control and Prevention, National Center for Emerging and Zoonotic Infectious Diseases (NCEZID), 2019a). The *A. phagocytophilum* reservoir is a smaller mammal such as the white-footed mouse (*Peromyscus leucopus*) (Centers for Disease Control and Prevention, National Center for Emerging and Zoonotic Infectious Diseases (NCEZID), 2019b).

Epidemiology

Ehrlichiosis is endemic to the southwestern and south-central United States, although cases are also being reported in Europe and Africa (Centers for Disease Control and Prevention, National Center for Emerging and Zoonotic Infectious Diseases (NCEZID), 2019a). Recent serology data show infections in South America, as well as China and Korea. Cases tend to increase in summer, especially between the months of June and July. During this time, the number of lone star ticks increased in the adult and nymph stages, which are the two stages that can transmit the disease to humans (Centers for Disease Control and Prevention, National Center for Emerging and Zoonotic Infectious Diseases (NCEZID), 2019a).

Anaplasmosis is most frequently reported in the upper Midwest and Northwestern United States (Centers for Disease Control and Prevention, National Center for Emerging and Zoonotic Infectious Diseases (NCEZID), 2019b). Cases have also been reported in central Europe (Slovenia and Sweden). Although cases can occur throughout the year, they are also in June and July when more infections are reported, coinciding with the time of the nymphal stage of ticks. In October and November there is a small peak of cases that coincides with the increased activity of adult ticks (Centers for Disease Control and Prevention, National Center for Emerging and Zoonotic Infectious Diseases (NCEZID), 2019b).

The number of cases reported by the Centers for Disease Control and Prevention (CDC) of ehrlichiosis caused by *E. chaffeensis* has been increasing gradually, going from 200 cases in 2000 to 2100 in 2019 (Centers for Disease Control and Prevention, National Center for Emerging and Zoonotic Infectious Diseases (NCEZID), 2019a). Between 2008 and 2012 the incidence was 3.2 cases per million people (Nichols Heitman et al., 2016). However, these data are not entirely correct since many cases cannot be confirmed serologically, asymptomatic infections are known, etc. However, while cases and incidence increased, largely due to improved diagnosis, fatality has dropped to 1% (Nichols Heitman et al., 2016).

Cases of infection by *E. ewingii* cannot be distinguished from those caused by *E. chaffeensis* if we look only at symptoms. 261 cases were reported to the CDC between 2008 and 2019, with no fatal cases (Centers for Disease Control and Prevention, National Center for Emerging and Zoonotic Infectious Diseases (NCEZID), 2019a). The incidence rate between 2008 and 2012 was 0.04 cases per million people and year (Nichols Heitman et al., 2016). It is possible that many *E. ewingii* infections are being diagnosed as *E. chaffeensis* infection because serologic tests do not discriminate (Nichols Heitman et al., 2016). Molecular tests are required to differentiate infection between the two species.

E. muris euclairensis infections have little impact on the population, with only 119 cases reported to the CDC since 2009 (Centers for Disease Control and Prevention, National Center for Emerging and Zoonotic Infectious Diseases (NCEZID), 2019a), with no reported deaths. Immunosuppressed patients have been shown to be more prone to the disease.

A. phagocytophilum is the species that causes the most infections. It has been increasing from 348 cases in 2000 to 5655 in 2019, going through a record in 2017 of 5762 cases (Centers for Disease Control and Prevention, National Center for Emerging and Zoonotic Infectious Diseases (NCEZID), 2019b). In the United States, during 2008 and 2012, it had an incidence of 6.3 cases per million inhabitants per year (Dahlgren et al., 2015). These data are thought to be incomplete since not all cases are reported, many cases are diagnosed clinically and not serologically, and furthermore, it is thought that due to the large number of tick bites, there must be many cases of asymptomatic disease. The fatality rate is less than 1% (Dahlgren et al., 2015).

Clinical manifestations

Ehrlichiosis and anaplasmosis usually present as acute diseases, but they include subclinical and self-limited cases together with cases of subacute and prolonged disease (Centers for Disease Control and Prevention, National Center for Emerging and Zoonotic Infectious Diseases (NCEZID), 2019a,b). Mild disease cases are associated with infection by *A. phagocytophilum*, with severe cases related to ehrlichiosis (Dahlgren et al., 2015; Nichols Heitman et al., 2016).

The incubation period is usually one to two weeks after the tick bite. Results have described that the incubation period can even drop to 5.5 days after the bite (Aguero-Rosenfeld et al., 1996).

Symptoms can range from mild-moderate to severe, depending on the immunocompromised state of the patient, as well as the delay in the administration of treatment.

As mild symptoms we find fever, chills, malaise, headache, nausea, vomiting, diarrhea, loss of appetite, arthralgia, myalgia, cough, confusion, and rash (Dumler et al., 1993; Centers for Disease Control and Prevention, National Center for Emerging and Zoonotic Infectious Diseases (NCEZID), 2019a,b). The rash appears more frequently in children and is a macular, maculopapular or petechial rash (Schutze et al., 2007; Sigurjonsdottir et al., 2017). The appearance of the rash is seen more frequently in ehrlichiosis (Bakken et al., 1996).

Subacute disease is characterized by long-lasting fever, with one case reported with fever lasting 50 days (Everett et al., 1994; Roland et al., 1995).

Cases of serious diseases are associated with elderly patients, immunocompromised status, transplantation or chronic disease (Bakken and Dumler, 2000; Wormser et al., 2006; Esbenshade et al., 2010). Symptoms of severe disease include meningoencephalitis, respiratory failure, disseminated intravascular coagulation, seizures, coma, multiple organ failure and death. In addition, heart failure and pericardial effusion may occur (Goodman et al., 1996; Vanek et al., 1996). Neurological symptoms are related to ehrlichiosis, being very rare in anaplasmosis. These symptoms can appear in up to 20% of patients and are usually mental changes, neck stiffness and meningoencephalitis (Ratnasamy et al., 1996). Septic shock has also been recorded from this type of infection (Dumler, 2005; Zhang et al., 2008). Finally, cases of hemophagocytic lymphohistiocytosis have been reported (Otrock et al., 2015; Johnson et al., 2017).

Ehrlichiosis infection in children is reported much more frequently than anaplasmosis. Symptoms for ehrlichiosis are fever, headache, myalgia, rash, nausea, vomiting and lymphadenopathy (Schutze et al., 2007), while for anaplasmosis they are usually fever, headache, malaise and intestinal discomfort (Sigurjonsdottir et al., 2017). Only a minority of children have severe ehrlichiosis disease, requiring some admissions to the intensive care unit (UCI) with hemodynamic and ventilatory support (Schutze et al., 2007).

Laboratory findings

In *E. chaffeensis* infections, leukopenia (the most common), thrombocytopenia, as well as elevated transaminases, lactate dehydrogenase, and alkaline phosphatase are frequently observed (Dumler et al., 1993; Otrock et al., 2015; Sigurjonsdottir et al., 2017). Leukopenia and thrombocytopenia also occur in *A. phagocytophilum* infections. Leukopenia due to lymphopenia occurs early in the disease and with the progression of the infection, a lymphocytosis characterized by atypical lymphocytes appears (Aguero-Rosenfeld et al., 1996). In patients with anaplasmosis, thrombocytopenia is more common than neutropenia (Bakken et al., 2001).

In those cases that present neurological symptoms due to *E. chaffeensis*, we can find modifications in the cerebrospinal fluid such as high levels of proteins and lymphocytic pleocytosis (Ratnasamy et al., 1996). In the rare cases in which there are neuronal symptoms in *A. phagocytophilum* infections, the cerebrospinal fluid is slightly altered (Bakken and Dumler, 2008).

Diagnosis

Presumptive diagnosis of HME and HGA is made through clinical and epidemiologic features. Febrile illness with laboratory abnormalities (leukopenia and/or thrombocytopenia), history of tick bite and outdoor activities during the spring or summer months in a resident of an endemic area provides strong evidence for the diagnosis of HME.

Laboratory diagnosis included: culture and isolation, detection of morulae in peripheral blood, detection of specific immune response, detection of specific DNA by polymerase chain reaction (PCR) and direct detection of bacteria in tissue samples by immunohistochemistry.

Culture and immunohistochemistry

Culture and isolation in tissue culture is the gold standard in diagnosis of HME and HGA, however, primary isolation may take more than 2 weeks to obtain results (Thomas et al., 2009).

Isolation of *Erhlichia* spp. from clinical samples is difficult (routine hospital blood cultures cannot detect the organism) and has low diagnostic sensitivity, so it is not used routinely in the laboratory.

Microscopic examination of blood smears or buffy coat preparations during the first week of illness might reveal intracytoplasmic inclusions (morulae) in infected circulating leukocytes. This method is rapid, but it is relatively insensitive compared with other confirmatory tests. Morulae are detected within monocytes in only about 3% of patients with HME. In contrast, they are seen in the cytoplasm of neutrophils in 25–75% of patients with HGA (Ismail and McBride, 2017).

Serology

The most widely used test for diagnosis of HME and HGA is the indirect immunofluorescence (IFA) antibody assay for IgG and IgM. Sera collected during the first 1–3 weeks after onset of illness may be negative (Dawson et al., 1990) and a second serum collected 2–3 weeks later is recommended. False negative results may occur if a patient is immunocompromised or was treated very early in the disease (Paddock and Childs, 2003; Ismail and McBride, 2017).

A single IgG positive result suggests current or previous infection. Specific IgG may remain detectable for months to years after disease has resolved.

A fourfold rise in IgG titer between acute serum and a convalescent serum collected 2–4 weeks later provides the best evidence of active infection. In most laboratories the minimum titer considered to be indicative of current or previous infection ranges from 1:64 to 1:80 (Chapman et al., 2006).

IgM antibodies against ehrlichiae and *A. phagocytophilum* have lower specificity than IgG antibodies (Brouqui et al., 2001) and therefore, IgM antibody titers should be interpreted carefully.

There are high rates of cross-reactivity between antibodies to *A. phagocytophilum* and those to *E. chaffeensis*, so generally, serologic testing for both pathogens should be performed in areas endemic for ehrlichiosis and anaplasmosis. If the titer is much higher for one organism than the other, the one with the higher titer should be considered the likely causative agent. Cross-reactivity has been described with other rickettsias, *Coxiella burnetii*, and infectious mononucleosis (Thomas et al., 2009).

Other techniques that have been used include enzyme-linked immunosorbent assays (ELISAs), but ELISA tests are generally qualitative and are generally not useful to monitor the changes in antibody titers.

PCR

PCR is the most sensitive and specific method for the detection and identification of *E. chaffeensis*, *A. phagocytophilum*, and *E. ewingii*. Whole blood and CSF are the most appropriate samples for PCR testing. The sensitivity of PCR is greatest during the 1 or 2 weeks of infection, decreasing over time. The sensitivity for detecting *A. phagocytophilum* is 67–90% and 60–80% for *E. chaffeensis*, depending on the time of onset of infection (Thomas et al., 2009; Salinas et al., 2010; Ismail and McBride, 2017). Treatment with doxycycline can decrease the sensitivity of PCR, so samples should be collected before initiation of treatment if possible (Dumler et al., 2007).

Treatment

Due to the delay in obtaining confirmatory test results treatment for ehrlichiosis or anaplasmosis is usually started before test results are available. When treatment is started early, most people respond rapidly and well. A delay in treatment may lead to serious complications, including death.

E. chaffeensis, *E. ewingii*, and *A. phagocytophilum* are universally susceptible to doxycycline. In adults, doxycycline can be given either orally or intravenously at a dose of 100 mg twice daily. People take this antibiotic until they improve and have had no fever for 24–48 h, but they must take it for at least 7 days. Children should be treated with doxycycline at a dose of 4.4 mg/kg per day, divided every 12 h, intravenously or orally. Treatment should continue for at least three days after defervescence. In general, the duration of treatment is 7–14 days. Treatment relapses or antibiotic resistance has not been reported.

Rifampicin can be given as an alternative to doxycycline for treatment of ehrlichiosis and anaplasmosis, but clinical experience is limited in anaplasmosis (Krause et al., 2003).

In cases of allergies to doxycycline, and in some pregnant patients for whom the clinical course of ehrlichiosis appears mild, physicians might consider treatment with rifampin. Antibiotics in prophylaxis are not recommended to prevent ehrlichiosis.

EDITOR-IN-CHIEF

Nima Rezaei gained his medical degree (MD) from Tehran University of Medical Sciences and subsequently obtained an MSc in molecular and genetic medicine and a PhD in clinical immunology and human genetics from the University of Sheffield, UK. He also spent a short-term fellowship of pediatric clinical immunology and bone marrow transplantation in the Newcastle General Hospital. Professor Rezaei is now the full professor of immunology and vice dean of International Affairs, School of Medicine, Tehran University of Medical Sciences, and the co-founder and head of the Research Center for Immunodeficiencies. He is also the founding president of Universal Scientific Education and Research Network (USERN). Prof. Rezaei has already been the director of more than 100 research projects and has designed and participated in several international collaborative projects. Prof. Rezaei is the editor, editorial assistant, or editorial board member of more than 40 international journals. He has edited more than 50 international books, has presented more than 500 lectures/posters in congresses/meetings, and has published more than 1100 scientific papers in the international journals.

FOREWORD

It is a great honor to be asked to introduce, with this foreword, the *Encyclopedia of Infection and Immunity*. This work will be read and enjoyed by many students, both graduate and postgraduate, including clinicians, laboratory practitioners, and scientists. Many colleagues have contributed to this important work, with over 230 original chapters assembled in sections and listed alphabetically. I offer my warm congratulations to the editors of this book, for soliciting a wide body of expertise and assembling it in a form that gives so much pleasure and information to the reader.

For those of us who work in the field of infection and immunity, the last two years have been exceptionally challenging. At the current time we are 22 months into a major pandemic caused by a novel coronavirus and its variants, and worldwide, sadly, there have been many hospitalizations and deaths. Clinicians and scientists in our field have been working flat out, caring for patients, generating or utilizing diagnostic tests, generating new knowledge in immunity to coronaviruses, or discovering, testing, and deploying new vaccines. Public Health practitioners have organized our medico-social responses to limit transmission and deal with the consequences of infection. Behavioral scientists have transformed our approach to informing the public, getting the best possible outcomes from effective communication. Governments have learned the danger of ignoring the expertise of scientists, and in many countries, the public look upon clinicians and scientists with gratitude and respect. It is a testament to the advancement of infection and immunity science that the genome of the virus was sequenced within a few weeks of COVID-19 emerging, and that within 12 months, the first trials of novel vaccines had been completed. These vaccines included some with exceptionally novel technologies, including the RNA vaccines and the viral-vectored vaccines.

Underpinning the academic agility of students and practitioners in Infection and Immunity is the universal strength of sound education. Readers of this book will be seeking the knowledge they need for a comprehensive understanding of infectious disease and immunology. We work in a fascinating discipline. Our field is unique in that pathogenesis involves at least two sets of genomes—on the one hand the microbe, and on the other, the host. The microbial genome programs its microenvironment to enable acquisition of and residence in a niche for sufficient time to replicate and further disseminate to other hosts. The human genome has evolved to tolerate and contain a wide range of symbionts and pathobionts, with highly sophisticated immune decision-making at the cellular level, but to respond to invading species with an elaborate coordinated repertoire of innate and acquired immunity. The complex conversation between many different microbes and the human host generates a wide range of disease phenotypes. This makes the job of an infectious disease physician so challenging but at the same time so fulfilling.

Our field is enriched by the many scientists and clinicians who are willing to share their experience with their peers and students. This book reflects the great variety of knowledge that has emerged over centuries of inquiry and endeavor, and I believe you will be rewarded by using it as one of your reference sources.

Robert C. Read

Editor-in-Chief, Journal of Infection

Professor of Infectious Diseases and Consultant Physician

University Hospital Southampton, United Kingdom

PREFACE

Although infections have been one of the most important health threats since centuries ago, the mechanisms of human defense against infections have been unclear until last century. The scientific world has remarkable progresses in the field of immunology during recent decades. Indeed, the novel discovery of genes related to different pathogens has enhanced our knowledge about the immune system. Understanding different pathogens and the immune mechanisms promote diagnostic strategies and design more efficient therapeutic agents.

Encyclopedia of Infection and Immunity is a comprehensive text, which covers topics not only on basic immunology and microbiology but also on clinical immunology and infectious diseases. Section 1 focuses on the immune system, while Section 2 describes the interaction between pathogens and immunity. Bacteria, viruses, fungi, protozoan parasites and helminths, and insect and mites are explained in Sections 3–6, respectively. Section 7 discusses the clinical infectious disease challenges, whereas clinical immunology is covered in Section 8. Laboratory tests and treatment protocols are the main focuses of Sections 9 and 10, respectively.

Encyclopedia of Infection and Immunity is the result of valuable contribution of more than 400 scientists from many well-known universities/institutes worldwide. I would like to hereby acknowledge the expertise of all contributors, for generously devoting their time and considerable effort in preparing their respective chapters. I would also like to express my gratitude to Elsevier for providing us the opportunity to publish this Encyclopedia.

Finally, I hope that this comprehensive book will be of special value for researchers and clinicians who wish to extend their knowledge on infection and immunity.

Nima Rezaei, MD, PhD

CONTENTS OF VOLUME 2

Section 4: Viruses, Edited by Nima Rezaei

Introduction on Viruses <i>Sara Momtazmanesh and Nima Rezaei</i>	1
Herpes Simplex Viruses Type 1 and Type 2 <i>Antonia Reyes, Mónica A Farías, Nicolás Corrales, Eduardo Tognarelli, and Pablo A González</i>	12
Epstein-Barr Virus <i>Jennifer M Geris, Lauren M Duval, and Henry H Balfour Jr</i>	37
Cytomegalovirus <i>MR Schleiss</i>	53
Adenoviruses <i>Paloma Hidalgo and Ramón A González</i>	59
Influenza Viruses <i>Shaghayegh Khanmohammadi and Nima Rezaei</i>	67
Paramycoviridae (Paramyxovirus, Measles Virus, Mumps Virus, RSV) <i>Dinh Toi Chu, Hue Vu Thi, Nguyen Thai Son, and Quang Canh Tran</i>	79
Papillomaviruses <i>Hoorieh Soleimanjahi and Ala Habibian</i>	86
Togaviridae and Flaviviridae <i>Tauqeer Hussain Mallhi, Nida Bokharee, and Yusra Habib Khan</i>	100
Hepatitis Viruses <i>Taravat Bamdad and Atefeh Yari</i>	113
Human Immunodeficiency Virus (HIV) <i>Thomas S Alexander and Ken S Rosenthal</i>	123
Reovirus and Rotaviruses <i>Hoorieh Soleimanjahi and Fatemeh Hosseini Heydarabadi</i>	131
Poxvirus <i>Rebecca K Lane and Yan Xiang</i>	146
Picornaviridae: Enterovirus <i>Zubair Anwar</i>	154
The Caliciviridae Family <i>Yoatzin Peñaflor-Téllez, Carlos E Miguel-Rodríguez, and Ana Lorena Gutiérrez-Escolano</i>	192
Bunyavirus <i>Natalia S Barbosa, Juan O Concha, and Luis LP daSilva</i>	207
Rhabdoviridae, Rabies Virus <i>Tomoaki Ogino</i>	219

Coronaviruses	241
<i>Dewald Schoeman, Bianca Gordon, and Burtram C Fielding</i>	
Parvoviridae	259
<i>Giorgio Gallinella</i>	
Arenaviruses	278
<i>Claudia S Sepúlveda, Sandra M Cordo, Cecilia A Vázquez, Cybele C García, and Elsa B Damonte</i>	
Ebolavirus and Other Filoviruses	292
<i>Ayato Takada</i>	
 Section 5: Fungi, Protozoan Parasites and Helminths	
Fungi, Edited by Fanny Lanternier	
Main Acquired Risk Factors of Different Fungal Diseases	301
<i>Pedro Puerta-Alcalde and Carolina Garcia-Vidal</i>	
<i>Candida</i> and Candidiasis	315
<i>Frederic Pereira and Blandine Rammaert</i>	
<i>Aspergillus</i> and Aspergillosis	330
<i>Sarah Sze Wah Wong, Sarah Dellière, Emmanuel Lafont, and Vishukumar Aimanianda</i>

What is a virus?

Viruses are very small infectious particles without a cellular structure lacking the ability to reproduce independently. They are all obligate intracellular parasites that can only regenerate by using the resources of an infected host cell. Viruses are comprised of protein packages containing genomic material, which can be either deoxyribonucleic acid (DNA) or ribonucleic acid (RNA) (Pellett et al., 2014). Notably, virus and virion are two concepts that may be used interchangeably commonly; however, they have some slight but crucial differences. The virion, also known as a virus particle, is the activated infectious extracellular form of the virus released from an infected cell and can bind to the surface of another cell spreading the virus. In contrast, the virus refers to the nucleoprotein particle at any time.

It is important to study viruses because of several reasons. Viruses have existed since the beginning of life and are critical in evolution. Moreover, they can be found almost everywhere in our surroundings, infecting a wide range of host cells from prokaryotes to eukaryotes. Most importantly, viral infections, such as viral respiratory infections (Monto, 2002) and human immunodeficiency virus (HIV) (Frank et al., 2019), impose an enormous burden on healthcare systems.

It has been more than a century since the discovery of viruses. The tobacco mosaic virus, a plant virus, was the first identified virus in the nineteenth century. In 1901, yellow fever was among the first viruses discovered to affect humans (Woolhouse et al., 2012). While the slope in discovering viruses has relatively decreased in the past decades, many viruses remain yet undiscovered, and there are a number of newly identified viruses each year (Woolhouse et al., 2012). Moreover, novel human viruses, such as the coronavirus SARS-CoV-2 (COVID-19), Ebola virus, and severe acute respiratory syndrome (SARS), can emerge due to variants of already known viruses (Ryu, 2017c). Notably, scientists were not able to actually see a virus until the 1930s, when electron microscopes were introduced (Fig. 1). In addition to electron microscopy, of note, X-ray crystallography is another technique to visualize virion structural organization. With its near-atomic resolution, X-ray crystallography can aid in localizing antigenic sites and further investigation of virion attachment and penetration to the host cells (Burrell et al., 2017a).

It is debatable whether viruses are inanimate or alive. The answer to this question entirely relies on the definition of a living organism. The discovery of exceptionally large and complex viruses with classic cellular genes disputed the notion of considering viruses as inanimate objects. However, due to the following reasons, it is proposed not to consider viruses as life forms. Although viruses contain genetic material similar to cellular organisms, they lack several fundamental features of cellular structures, such as self-maintenance and self-replication. Moreover, having a common ancestry has been observed in living cellular organisms, while this feature is missing in viruses. Lastly, unlike cellular organisms, viruses do not have the required genes for protein synthesis and carbon and energy metabolism independently. Therefore, they are dependent on the host cells for replication (Moreira and Lopez-Garcia, 2009).

The diverse world of viruses

Viruses can be extremely diverse. Their size may vary from 20 nm (Duan, 2006) to 2500 nm (Okamoto et al., 2017). Their genetic material can have a large variety in its structure, with genome sizes ranging from approximately 800 bp (Campillo-Balderas et al., 2015) to 2.7 Mb (Legendre et al., 2019). They have wide-ranging hosts and habitats. They can cause different infection patterns and replication cycles lasting for a few minutes to several days (Payne, 2017). This broad diversity highlights the critical role of viruses in living systems.

The origin of viruses

Three principal hypotheses provide explanations for the origin of viruses, namely “the virus-first”, “the progressive (escape)”, and “the regressive (reduction)” hypotheses.

According to the virus-first theory, viruses existed before the emergence of cellular structures and were the first self-replicating units (Koonin and Martin, 2005). Notably, it is postulated that RNAs (not DNAs) were the first replicating molecules. Based on this notion, these first replicating entities evolved into more complex and organized structures, leading to the formation of cells. Moreover, some have argued that the antecedents of nucleocytoplasmic large DNA viruses (NCLDV) may have resulted in the emergence of eukaryotic organisms (Bell, 2001). NCLDVs comprise a diverse group of more complex viruses, such as mimivirus, a giant virus with a total diameter of approximately 750 nm and containing biosynthetic enzymes that are usually not present in other viruses (Claverie, 2008).

Conversely, the progressive and the regressive hypotheses hold the notion that cellular organisms existed before viruses. The progressive hypothesis states that genetic pieces with the ability to move within the genome attained the capacity of exiting one cell and entering another. The remarkable resemblance between the genetic arrangement in retroviruses and retrotransposons, a major component of the eukaryotic cells, supports this notion. As a result, it can be presumed that gaining a few structural proteins helped the genetic particle to escape the cell and enter a new one.

As opposed to the progressive hypothesis, the regressive hypothesis holds the assumption that viruses were initially free-living entities that began symbiotic relationships with other organisms. Over time, they developed a more parasitic relationship and lost their complexity as they became dependent upon their hosts for replication. The regressive hypothesis mainly hinges upon NCLDVs, which are more complex and larger compared to most other viruses (Wessner, 2010).

Viral structure and anatomy

All viruses are composed of two main structures, namely capsid and nucleic acid. On the other hand, most viruses are enveloped; however, some are non-enveloped or naked. These structures are described below (Harrison, 2013) (Fig. 2).

Capsid

The capsid is a dynamic protein package comprised of an assembly of a large number of capsid protein copies that can either have a single or a few types. The primary role of the capsid is to protect the genome. Additionally, particularly in the non-enveloped viruses, the capsid facilitates the attachment and penetration of the virus to the host cell. The capsid proteins are chiefly bonded by electrostatic interaction (van der Waals interaction), creating capsid protein building blocks. Only a few covalent bonds are developed between the building blocks to allow the capsid to be flexible enough to let the genome release whenever necessary (Mateu, 2013). As a result of the repeated same protein-protein interfaces, the capsid is most commonly symmetrical (Mateu, 2013). There are three main capsid shapes as described in the following.

- Helical:** capsid proteins are assembled in a circular manner resembling a stack of discs that are attached helically, creating a central cavity as a place for the nucleic acid. Tobacco mosaic virus, arenaviruses, and bunyaviruses are some examples of viruses with a helical capsid.
- Icosahedral:** The capsid is comprised of equilateral triangles, commonly composed of an arrangement of three capsid proteins merged together in a spherical shape. The capsid, which is formed in a stepwise manner, has no gaps in between and fully encompasses the genome. Poliovirus, herpesvirus, papillomavirus, rhinovirus, and adenovirus are some examples of viruses with an icosahedral capsid.
- Complex:** A complex capsid is a combination of helical and icosahedral shapes. Viruses with complex capsid may have a head-tail morphology (an icosahedral-shaped head with a helically shaped tail), a distinctive feature of viruses infecting bacteria called bacteriophages. The bacteriophage attaches to the bacterium using the tail. Then they create a hole in the cell wall and insert their DNA into the bacterium using their tail as a channel.

Nucleic acid

Viral genomic material has a wide diversity. It can be DNA or RNA, single- stranded (ss) or double-stranded (ds), circular or linear, and monopartite or multipartite. Of note, in viruses with a monopartite genome, all genes are encoded by a single nucleic acid molecule, while in those with a multipartite genome, genes are encoded by multiple or segmented nucleic acid molecules. Except for retroviruses, which have a diploid genome, all other viruses are haploid. Notably, the capsid and the nucleic acid are collectively called nucleocapsid (O'Carroll and Rein, 2016).

Fig. 2 Two enveloped viral particles with spherical (on the left side), and helical (on the right side) capsids are depicted. Adapted from Wang-Shick R (2017) Virus structure. In: Wang-Shick R (ed.), *Molecular Virology of Human Pathogenic Viruses*, pp. 21–29, Academic Press, ch. 2, with permission.

Envelope

It is a lipid bilayer structure encircling the nucleocapsid. The envelope is derived from either plasma membrane, nuclear membrane, the membrane of the Golgi apparatus, or the endoplasmic reticulum of the host cell. Matrix proteins are structural proteins connecting the envelope with the capsid with a critical role in viral assembly (Burrell et al., 2017c; Ryu, 2017b).

Viral genetics

The vast diversity between viruses is partly owing to the various mechanisms they employ to create genomic changes. The key concepts of viral genetics are described in the following (Fig. 3).

Recombination

Recombination is the exchange of genetic material between at least two viruses when they co-infect the same host cell by crossing over within regions with significant base sequence similarity (Perez-Losada et al., 2015).

Reassortment

Reassortment is exclusively seen in viruses with a segmented genome. It is defined as the exchange of intact genes within the entire segment, which occurs during coinfection. Reassortment has been observed in Bunyaviridae, Reoviruses, arenavirus, and Orthomyxoviruses. Reassortment can result in drastic changes over a short period. For instance, the 2009 novel H1N1 influenza pandemic emerged as a result of a triple reassortment between avian, human, and swine viruses. Antigenic shift, which occurs when a virus has a mixture of surface antigens from two or more viruses, may be a consequence of reassortment (Lowen, 2018; Neumann et al., 2009).

Phenotypic mixing

Phenotypic mixing also occurs during coinfection. In this case, a virus's genome becomes completely or partially coated with surface proteins of another virus (forming a pseudovirion). Notably, the infectivity of the hybrid agent is determined by the surface proteins. Although, the progeny of the hybrid agent will be the same as the primary virus again (Loverdo and Lloyd-Smith, 2013).

Fig. 3 The four major genomic changes in the viruses: (A) recombination, (B) reassortment, (C) phenotypic mixing, and (D) complementation.

Complementation

When a virus has a mutated gene resulting in a non-functional protein, to infect its host, it requires the presence of another virus with the non-mutated function form of that gene. For example, the hepatitis D virus carries a mutated version of one of the key envelop proteins (hepatitis B surface antigen (HBsAg)). Therefore, replicating hepatitis B virus is necessary for the infectivity of hepatitis D virus.

Classification of viruses

Two main classifications are adopted to organize viruses into different groups, namely the International Committee on Taxonomy of Viruses (ICTV) and the Baltimore classifications.

The ICTV taxonomy, first introduced in 1971, aims to classify the great number of discovered viruses into a single classification system while demonstrating their evolutionary relationships, i.e., their phylogenies (International Committee on Taxonomy of Viruses (ICTV), n.d.; Adams et al., 2017). The current taxonomy database is freely accessible online (<http://ictv.global>) (Lefkowitz et al., 2018). The 2019 version of the ICTV taxonomy encompasses 15 ranks, shown in Fig. 4 (Gorbalenya and Siddell, 2021; Walker et al., 2019). Fig. 5 describes virus taxa infecting vertebrates.

The Baltimore classification, a genome-based classification of animal viruses, was first proposed by David Baltimore in 1971. According to the Baltimore classification, viruses are divided into seven groups based on the way of synthesizing their mRNAs. The

Fig. 4 The 15 ranks included in the 2019 version of the ICTV taxonomy (The nomenclature is shown in the parentheses.)

Fig. 5 Illustration of viral taxa infecting vertebrates. Adapted from King AM, Adams MJ, Carstens EB, Lefkowitz EJ (eds.) (2012) *Virus Taxonomy: Ninth Report of the International Committee on Taxonomy of Viruses*. p. 20, Elsevier Academic Press: San Diego, CA, with permission.

following characteristics are considered in the Baltimore classification: (1) whether the genome is composed of DNA or RNA, (2) genome strandedness (either single- or double-stranded), and (3) for single-stranded genome, whether it is positive or negative sense. Overall, DNA viruses are in groups I and II, RNA viruses are in groups III, IV, and V, and reverse transcribing viruses are in groups VI and VII. Viruses with a double-stranded DNA genome are classified under Group I. Viruses with a single-stranded DNA

genome are within Group II. In these viruses, the single-stranded DNA is first converted to the double-stranded form before being used as a mRNA transcription template. Viruses with a double-stranded RNA genome are categorized as Group III. In this group, mRNA is produced from RNA transcription. Viruses with a positive-stranded RNA genome are classified as Group IV. In these viruses, the genomic RNA is directly utilized as mRNA (Baltimore, 1971).

On the other hand, group V is comprised of viruses with a negative-stranded RNA genome. Therefore, in these viruses, transcription of the RNA genome template leads to mRNA synthesis. Even though in groups VI and VII, the genome is either single-stranded RNA (Group VI) or double-stranded DNA (Group VII) but they are classified as reverse transcribing viruses and not as DNA or RNA viruses. This is because there are DNA and RNA intermediates in the life cycle of group VI and VII viruses, respectively. Notably, in all reverse transcribing viruses, the viral DNAs are a product of reverse transcription (Ryu, 2017a; Burrell et al., 2017b).

Viral replication

Overall, the viral replication cycle can be divided into three major phases: viral entry, genome synthesis, and release.

1. Viral entry: this stage comprises four steps, as described below:
 - 1.2. Attachment: The attachment is the first encounter between the virus and the host cell. Two main categories of proteins on the host cell membrane are involved in the attachment stage, including attachment factors and viral receptors. The attachment factors, such as glycoaminoglycans like heparan sulfate proteoglycan (HSPG) and low-density lipoprotein (LDL) receptors, aid in the interaction between the viral receptors and a diverse variety of viral particles. Conversely, viral receptors such as the cluster of differentiation (CD)4 and sialic acid are virus-specific. The interaction of these viruses with the viral particles enhances viral penetration. Notably, the presence of a viral receptor is a key determining factor in the susceptibility of a host cell to a particular virus.
 - 1.3. Penetration: After viral attachment, the viruses penetrate into the cytoplasm via two major mechanisms, mainly based on whether they are enveloped or not. The enveloped viruses can undergo either direct fusion or receptor-mediated endocytosis (Plempner, 2011). In the former mechanism, the nucleocapsid enters the cytoplasm directly after the diffusion of the viral envelope and the host cell plasma membrane. Therefore, the envelope does not enter the cell. Retroviruses are a characteristic example of viruses penetrating the host cell via direct fusion. However, most viruses penetrate into their target cell via receptor-mediated endocytosis. In this mechanism, following the interaction of the virus and its receptor on the plasma membrane of the host cell, a coated pit is formed, and an endosome encompasses the viral particle. At this step, the nucleocapsid should be released into the cytoplasm following an endosomal breakdown. The mechanism of endosomal breakdown differs between enveloped and non-enveloped viruses. In case the virus is enveloped, the low pH of the endosome triggers activation of the fusion peptide, resulting in the diffusion of the envelope with the endosomal membrane. In non-enveloped viruses, one of the capsid proteins induces endosomal lysis. Receptor-mediated endocytosis has two important advantages over the direct fusion mechanism. First, unlike the direct diffusion method, the viral envelope can enter the host cell as well. Second, in direct diffusion, the cell cortex can act as a physical barrier for the virus particle. However, this barrier is bypassed in receptor-mediated endocytosis.
 - 1.4. Intracellular trafficking: Subsequent to penetration, the nucleocapsid moves to the proper site within the cell via intracellular trafficking to initiate the genome replication phase. For most RNA viruses, viral replication occurs in the cytoplasm. On the other hand, most DNA viruses need to enter the nucleus for gene replication. Generally, the viral particles are transported to the appropriate location within the cytoplasm, particularly the perinuclear area, via microtubule-mediated transportation. The interaction between dynein, a molecular motor protein, and either viral capsid or endocytic vesicles mediates the transportation (Robinson et al., 2018).
 - 1.5. Uncoating: In this process, the viral genetic material is released following the removal of the capsid. Viral uncoating is induced by multiple factors and usually occurs during intracellular trafficking. The most common trigger is the gradual decrease of the endosomal pH. The virus is transferred via a nuclear pore using different mechanisms, mainly depending on its genome size in case it requires to enter the nucleus for replication. If the nucleocapsid is small enough to pass the nuclear pore, like polyomavirus, it enters the nucleus directly, and the uncoating process occurs in the nucleus. For larger viruses, the capsid and the nuclear pore interaction results in some structural changes in the capsid, permitting transportation of the DNA genome into the nucleus (Kilcher and Mercer, 2015).
2. Viral genome and protein synthesis: Viral replication includes genome synthesis and transcription of viral proteins. Viruses may exploit various mechanisms to replicate their genome, mainly according to the type of viral nucleic acid. In most viruses, the replication is primarily done by host cells' proteins and enzymes. Most dsDNA viruses enter the nucleus for replication and use cellular DNA polymerase and RNA polymerase.

For dsDNA viruses, transcription occurs in two phases. In the first step, the immediate early and/or early genes are transcribed, most of which facilitate the replication process. Nevertheless, the majority of the proteins involved in the virion structure are called late genes as they are transcribed in the second phase. As an exception, poxviruses contain all of the necessary genes for encoding proteins that are required in the replication process. Therefore, they do not enter the nucleus, and their replication occurs in the cytoplasm.

ssDNA viruses commonly enter the nucleus, and their genome is converted to dsDNA by DNA polymerase during the S phase of the cell cycle. Subsequently, RNA polymerase II leads to transcription of the viral genes, and the genome is replicated by DNA polymerase.

In contrast to most DNA viruses, RNA viruses typically do not enter the nucleus. The cellular RNA polymerase II requires a DNA template and cannot transcribe the RNA. As a result, all RNA viruses encode RNA-dependent RNA polymerase to transcribe their mRNA. The cellular ribosome translates the produced mRNA to form the viral proteins. For viruses with ssRNA, their replication varies depending on whether they are positive or negative sense. The genome of positive-strand RNA viruses can be directly translated, while for negative-strand RNA viruses, it needs to be copied into a positive sense RNA via viral RNA-dependent RNA polymerase before translation (Rampersad and Tennant, 2018).

3. Viral exit: Viruses exit the host cell in three stages: (1) capsid assembly, (2) release, and (3) maturation.
 - 3.2. Capsid assembly: Capsid proteins may come together and form the capsid spontaneously (particularly in viruses with simple icosahedral capsid), or they may also require scaffolding proteins or simultaneous interaction of the viral nucleic acid and capsid proteins. For instance, in picornaviruses, the immature capsid (procapsid) is first formed, and the RNA genome is delivered into the capsid later. On the other hand, in adenoviruses, capsid assembly and genome packaging occur at the same time (Mateu, 2013).
 - 3.3. Release: Most non-enveloped viruses, such as adenoviruses and polyomaviruses, are released subsequent to host cell lysis, which kills the host cell. However, enveloped viruses need to undergo envelopment before their release. Envelopment can occur either after the capsid development, the example of which are herpes viruses, or at the same time as capsid assembly, an example of which are retroviruses. The bilayer envelop may originate from the host cell's plasma membrane or intracellular organelles, including the Golgi apparatus or endoplasmic reticulum. For instance, the envelope of retroviruses and influenza viruses is derived from the plasma membrane, while the envelope of hepatitis B viruses and herpesviruses originate from endosomes. Following the envelopment process, viruses that have traveled through the endoplasmic reticulum and Golgi apparatus are released via exocytosis. In the budding mechanism, viral proteins are recruited together at the budding site, and the host cell's plasma membrane or endosomal membrane composes the viral envelope (Louten, 2016b).
 - 3.4. Maturation: Many viruses need to undergo irreversible changes extracellularly after their release from the host cell to activate their infectiousness. For example, retroviruses require to undergo morphological changes, such as compacting their capsid structure by cleavage of some of their proteins (Ryu, 2017d).

An introduction to disease course in viral infections

Viral infections may have a wide variety of presenting patterns. Even within the same viral family, the disease may be asymptomatic or symptomatic, with a spectrum ranging from mild to severe manifestations. For instance, in infection with COVID-19, approximately 20% of the patients are asymptomatic (He et al., 2021), while near 20% develop severe or critical disease, and most of the patients have mild symptoms (Wu and McGoogan, 2020).

Viral infections may be transient or persistent and local or systemic (Burrell et al., 2017e). Commonly, viral infections are divided into two major groups, namely productive and non-productive infections, based on viral reproduction in the host's body, as explained below.

1. Productive infections: In these infections, the virus successfully infects the host cell resulting in an ongoing viral production (King et al., 2007). Productive infections can be divided into two sub-categories: lytic infection and persistent infection.
 - 1.2. Lytic infection: In viruses causing a lytic infection, viral replication occurs through the host cell's lysis and death. Therefore, these viruses typically cause transient infections, which may be localized or systemic. Like many common respiratory viral diseases, infections caused by adenoviruses and influenza viruses are classic examples of transient localized lytic infections. These viruses typically have an incubation period of 2–5 days, followed by the onset of symptoms. The viral replication peak usually occurs before and after symptom onset, during which the patient has a higher chance of transmitting the infection to others (Greber, 2020; Thangavel and Bouvier, 2014).

In contrast to the mentioned examples, transient infections may be systemic, such as varicella-zoster virus infections. In the first stages of the disease, the virus replicates in the upper respiratory tract. It enters circulation by infecting T cells leading to a systemic spread to the skin and other organs (Gershon et al., 2015).

- 1.3. Persistent infection: The virus has an ongoing replication for a considerable time. These viruses either do not cause cell death or have durable reservoir cells should they result in cell death. Infections with hepatitis B and hepatitis C viruses are examples of the former mechanism, causing systemic diseases. During the acute phase of the disease, virus replication occurs in the liver resulting in the movement of viral antigens into the blood. In this stage, hepatic damage happens due to the immune response mediated by cytotoxic T lymphocytes destroying cells infected with the virus. In most cases, the infection resolves within 3–4 weeks. Although, approximately 5% of the patients develop persistent infection. Persistent hepatitis B infection is a major cause of cirrhosis and a predisposing factor for hepatocellular carcinoma (D'Souza and Foster, 2004). Conversely, most of the patients infected with hepatitis C cannot fully recover and develop chronic infection. (Webster et al., 2015).

On the other hand, while HIV infection can lead to cell death, it causes a persistent infection owing to its reliable reservoir cells. HIV targets CD4⁺ cells, particularly lymphocytes, and upon entrance to the host cell, the ssRNA is transformed to dsDNA by reverse transcriptase enzyme within the cytoplasm. Subsequently, the viral dsDNA integrates into the host cell's genome following entering the nucleus. During the initial phase, there is a considerable amplification of the virus resulting in the destruction of the lymphocyte. However, these lymphocytes are rapidly replaced and the viral reservoir facilitates persistent infection. Nevertheless, after the prolonged asymptomatic phase, approximately 10 years, the number of CD4⁺ lymphocytes gradually decline (Chosn et al., 2018; Chun and Fauci, 2012).

2. Non-productive infections: Opposing to the productive infections, during non-productive infections, the virus either does not have the ability to produce infectious progeny or it only has a limited capacity of replication (Payne, 1999). Non-productive infections can be divided into three sub-categories:
 - 2.2. Latent infection: In these infections, the host cells carry the viral genome for their lifetime; however, the virus does not commonly produce a progeny, and only a limited proportion of their genome might be expressed. Nevertheless, the infection may reactivate spontaneously at any time. All herpes viruses, including herpes simplex virus (HSV), varicella-zoster virus, Epstein Bar virus (EBV), and cytomegaloviruses, can cause latent infection. HSV and varicella-zoster virus reside in neurons, while EBV and cytomegaloviruses persist in lymphocytes that, unlike neurons, proliferate and have a shorter life span. These viruses are typically unintegrated. However, the EBV may integrate into the host's chromosome at low frequency (Morissette and Flamand, 2010). There are two types of HSV, namely HSV1 and HSV2. Both types, particularly HSV2, can cause genital lesions. HSV1 mainly results in oral infections. The majority of the new infections are asymptomatic. Following entering into the epithelial cells via skin or mucosa, HSV begins to replicate. Subsequently, the free sensory nerve endings take up and transport the nucleocapsid from the dermis to the nucleus in the sensory ganglion via retrograde axonal flow. Therefore, HSV becomes a persistent unintegrated infection. At any time, the virus can reactivate and travel back through the sensory nerve to the skin or mucosa. Several factors, such as stress, trauma, and immunosuppression, can trigger reactivation (Gupta et al., 2007). Herpes zoster, also known as shingles, is another unintegrated latent infection caused by reactivation of the dormant varicella-zoster virus in the dorsal horn nerve cells. Almost every individual is at risk of developing shingles due to either having chickenpox during their childhood or receiving the varicella-zoster virus vaccine. It typically occurs at older ages, and the most common trigger is weakened immune responses (Randolph, 2015).
 - 2.3. Transforming infection: It occurs when the viral genome integrates into the host's genetic material without producing progeny. These infections are usually predisposing factors for cancers. Infection with human papillomavirus is an example of this category, which can become persistent in a subset of the patients and can cause cervical cancer (Sudenga and Shrestha, 2013).
 - 2.4. Abortive infection: When the virus fails to produce infectious progeny despite infecting the target cell, it results in an abortive infection (Cohen et al., 2020).

An introduction to viral transmission

Like any other infectious agent, viruses can transmit via two major modes of (1) direct and (2) indirect. Notably, a virus may have several routes of transmission. Moreover, in humans, viruses can have multiple entry routes, including the respiratory tract, alimentary tract, genitourinary tract, skin, and eyes (Burrell et al., 2017d; Van Seventer and Hochberg, 2017).

Direct transmission: The virus is directly transferred from a reservoir to a predisposed host via either direct contact or droplet spread.

1. Direct contact: The infection is transmitted as a result of direct contact of bodily tissues or fluids of an infected person with another individual, such as skin-to-skin contact, kissing, and sexual intercourse. The virus may enter the body of the exposed person through damaged skin barriers or mucosal membranes, like the eyes and mouth. Scratches or bites can lead to direct inoculation. Importantly, blood borne viral infections, such as hepatitis B virus and HIV, can cause direct contact transmission (Beltrami et al., 2000).
 - 1.2. Droplet spread: Droplets are defined as short-range and fairly large (larger than 5–10 µm in diameter) aerosols produced by talking, singing, coughing, or sneezing. Droplets containing the virus can spread the disease via entering through the mouth, nose, or eyes. Additionally, this transmission route can be seen in respiratory viruses like the respiratory syncytial virus (Goldmann, 2000).
 - 1.3. Indirect transmission: In contrast to direct transmission, in indirect transmission, inanimate objects (fomites or vehicles), animate intermediaries (vectors), or air particles transfer the virus from its reservoir to the host. These intermediaries are described in the following.
2. Airborne: Dust or droplet nuclei, which can remain suspended in the air for a prolonged duration and spread over vast distances, transfer the virus. Compared to droplets, the smaller size of droplet nuclei (smaller than 5 µm in diameter) results in its prolonged suspendability. Airborne dust comprises viral materials that are on surfaces and again become suspended via airflow, like the wind. Measles morbillivirus, varicella-zoster virus, SARS virus, Middle East respiratory syndrome (MERS) virus, and SARS-CoV-2 can have airborne spread. These viruses can potentially result in epidemics and pandemics (Morawska et al., 2020; Louten, 2016a).

- 2.2. *Vehicleborne*: The viral infection is transmitted through vehicles, including inanimate objects (fomites), biological products, food, or water. Fomite transmission plays a crucial role in the spread of respiratory and enteric viral agents (Boone and Gerba, 2007). Additionally, adenovirus, astrovirus, hepatitis A, and Norwalk-like caliciviruses are examples of water-transmitted or food-transmitted viruses (Gall et al., 2015; Koopmans et al., 2002). Usually, the vehicle passively carries a pathogen. However, it can also provide a nourishing environment for the infectious agent.
- 2.3. *Vectorborne*: The infectious agent is transmitted from animals to humans or between humans by living organisms called vectors. The vector is commonly a bloodsucking insect. The viral agent enters into the insect after a blood meal from an infected host (either animal or human). The bite of the infected insect can infect another host. Most of the time, once a vector becomes infectious, it can transmit the disease for the rest of its life during each bite or blood meal. Zika virus, West Nile virus, Dengue fever, yellow fever, and chikungunya are mosquito-transmitted viruses (Allison et al., 2019).

The mentioned mechanisms explained the horizontal transmission of viral infections. In horizontal transmission, the infection spreads among the members of the same generation. On the other hand, in vertical transmission, the viral agent is passed from the mother to the offspring.

Three main mechanisms can result in vertical transmission. First, the viral genome embedded in the germ-line genes or encoded as episomes in the gametes can predispose the infant to the viral disease. Nevertheless, this route of transmission has not been reported in any human virus. Second, an infected mother can pass the infection to her fetus via transplacental spread during pregnancy. Rubella, cytomegalovirus disease, and Zika virus encephalitis, and microcephaly can be transmitted during pregnancy via the placenta. Third, contact with infected genitalia secretion or bowel material during delivery can result in perinatal transmission. Coxsackieviruses and HSV 1 and 2 can spread by this route during delivery. Of note, HIV and hepatitis B virus can have both transplacental and perinatal transmission (Burrell et al., 2017d).

Other non-living infectious agents

Viruses are not the only non-living infectious agents. Prions and viroids are infectious agents known as subviral particles that are smaller than viruses. Viroids consist of only a single strand of circular RNA without the ability to code proteins. For a very long time, they were known only to infect plants. However, recently, they have also been found in humans in infection with hepatitis D virus (Flores et al., 2012). Prions are made of proteins without any genetic material. The most common disease caused by prions in humans is Creutzfeldt-Jakob disease (CJD), a fatal disease characterized by rapidly progressive memory loss and neurological symptoms. Prion proteins (PrP^{Sc}) are β -sheet-rich isoforms of cellular prion proteins (PrP^C). It is postulated that the interaction of PrP^{Sc} with the PrP^C changes their conformation of PrP^C, resulting in aggregation of misfolded proteins. The deposition of proteins leads to neurodegeneration, which is mainly immune-mediated (Aguzzi et al., 2008).

Introduction

Herpes simplex viruses type 1 (HSV-1) and type 2 (HSV-2) are two members of the *Herpesviridae* family, and more specifically, the *Alphaherpesvirinae* subfamily that are highly prevalent in the world population (Boehmer and Nimonkar, 2003). In 2016, the global prevalence of HSV-1 infection was estimated at 66.6% for individuals aged 0–49, with approximately 5042 million people aged 0–99 being infected with this virus worldwide (James et al., 2020). For HSV-2, the global prevalence was estimated at 13.2% for individuals aged 15–49, which corresponds to 3736 million people at the time of the study (James et al., 2020).

Fig. 1 Tissues affected by HSV infection and HSV-related diseases. Body sites affected by herpes simplex viruses include the facial area (herpes simplex keratitis, conjunctivitis, retinitis, gingivostomatitis and herpes labialis—oral herpes), the brain (meningitis, encephalitis and Mollaret's syndrome), the torso and neck (eczema herpeticum, herpes gladiatorum and herpetic whitlow), and the genitalia (herpes genitalis).

Herpes simplex viruses (HSVs) are known to establish lifelong infections and cause a wide range of clinical manifestations such as *Herpes labialis*, herpes simplex keratitis, genital herpes, and herpes simplex encephalitis, among others (Fig. 1) (Suazo et al., 2015b). Furthermore, genital HSV infections have been reported to increase the risk of HIV infection, which raises concerns about co-infections (Suazo et al., 2015b). Given their importance at the public health level, numerous approaches aimed at treating and preventing infections with these viruses have been investigated over time, with many strategies currently being evaluated in clinical trials (Chung and Sen, 2012; Álvarez et al., 2020). However, currently, there are no vaccines available to prevent infections by HSVs. Nevertheless, numerous attempts for creating a vaccine against these viruses have been made using different schemes, such as subunit approaches, mutant viruses, and replication-deficient viruses, among others (Chung and Sen, 2012).

Importantly, HSVs have evolved different strategies to evade the immune response of the host. After primary infection, HSVs can evade the immediate cellular antiviral response through the interference of signaling pathways related to pathogen recognition by host receptors, by modulating the interferon pathway while also altering differentially the viability of immune and non-immune cells (Suazo et al., 2015a; Retamal-Díaz et al., 2016; Tognarelli et al., 2019). These viruses can also interfere with the innate immune response, such as with the functions of natural killer (NK) and natural killer T (NKT) cells, and by interfering with the activation of the complement (Suazo et al., 2015a; Tognarelli et al., 2019). These viruses have also been reported to interfere with the viability, and T cell-activating capacities of dendritic cells (DCs), which are crucial for mounting and regulating effective antiviral responses (Retamal-Díaz et al., 2016; Carreño et al., 2011). Moreover, HSVs also interfere with adaptive immune components by hampering both, humoral and T cell immunity (Retamal-Díaz et al., 2016).

In this article, we provide an overall perspective of herpes simplex viruses by discussing aspects related to their epidemiology, characteristics of the diseases they produce, current treatments available to counteract their effects, as well as research on new drugs and vaccines. Furthermore, we review aspects related to their structure, lifecycle and, finally, how they interfere with the host antiviral response.

Epidemiology and HSV-related diseases

Incidence and prevalence of HSV infections

Primary infections with HSV-1 mainly occur at a young age. In developing countries, approximately one-third of the population is HSV-1 seropositive by age five; however, in developed countries only one-fifth of the population is estimated to be infected by this age (Whitley and Roizman, 2001). On the other hand, HSV-2 infections usually occur at a more advanced age, with a seroprevalence of 13.2% in people aged between 15 and 49 as determined in 2016 (James et al., 2020). It has also been shown that the prevalence of HSV-2 infections varies depending on the global region, ranging from 5% for countries like Spain and England, approximately 20–30% for countries like Sweden and Germany, and up to 70% for the Sub-Saharan Region in Africa (Suazo et al., 2015b). A world health organization study in 2016 estimated that 3752 million people in the world aged between 0 and 49 years were infected with

HSV-1, with a prevalence of 66.6% (James et al., 2020). It was also estimated that 1290 million people aged 50–99 were infected with HSV-1 (at any site; James et al., 2020). Regarding the individuals affected with oral infections by HSV-1, it was estimated in 2016 that 3583 million people aged 0–49 were infected, with a prevalence of 63.6% (James et al., 2020). The highest number of individuals orally infected with HSV-1 were located in the South-East Asia Region, followed by the Western Pacific Region (James et al., 2020). Genital infection with HSV-1 in 2016 was found to affect globally 192 million people aged 15–49, equivalent to a prevalence of 5.2%. The highest number of individuals affected by this type of infection were located in the Americas Region, followed by the European Region (James et al., 2020).

On the other hand, it was estimated that a total of 491.5 million people aged 15–49 worldwide were living with HSV-2 infection in 2016 (James et al., 2020). The African Region was the most affected by this type of infection, followed by the Western Pacific, South-East Asia, and the Americas Regions. Furthermore, a study estimated that globally 344.5 million people aged 50–99 were infected with HSV-2 that year (James et al., 2020). Overall, the estimated prevalence of HSV-2 in the global population was 13.2%, with 3736 million people aged 15–49 being affected, with those in the Africa Region having the highest number of people infected, followed by the Americas Region (James et al., 2020).

Interestingly, it has been estimated that worldwide 596.0–655.7 million people aged 15–49 have had either HSV-1, HSV-2, or both HSV-1 and HSV-2 genital infections. These numbers are equivalent to 16.0–17.6% of the global population (James et al., 2020). Noteworthy, HSV-1 is more frequently detected during primary genital herpes than HSV-2, yet the latter is more commonly detected in genital herpes recurrences, which is likely due to the different reactivation rates of these viruses from this site of infection (Koren and Decker, 2016; Coyle et al., 2003; Pereira et al., 2012; Samra et al., 2003).

Regarding the global incidences of HSVs, for HSV-1 it has been estimated that 120.4 million people aged 0–49 became infected in 2016, equivalent to a 2.1% of incidence. The incidence of HSV-2 has been estimated at 0.6% for people aged 15–49, equivalent to 23.9 million individuals during 2016 (James et al., 2020). The worldwide incidence of neonatal herpes infection was estimated at 14,257 cases during 2010–15, equivalent to a global rate of 10.3 per 100,000 births when averaged across all regions, with two-thirds of the cases due to HSV-2 (Looker et al., 2017b), and the largest number of cases occurring in Africa. This finding correlates with a high incidence and prevalence of HSV-2 infections in adult women and high birth rates in this region (Looker et al., 2017b; James et al., 2020). Interestingly, in the Americas, Europe, and Western Pacific Regions, HSV neonatal infection was more frequently caused by HSV-1 than HSV-2 (Looker et al., 2017b).

HSV-associated diseases

Herpes simplex viruses cause a wide range of clinical manifestations such as skin-related diseases, ocular complications, central nervous system-related pathologies, and genital infections (Suazo et al., 2015b). While HSV-1 infections are commonly associated with orofacial lesions and HSV-2 with genital ones, infections with either virus may occur at these sites, although HSV-2 infection has been rarely diagnosed in the orofacial area, possibly because of infrequent HSV molecular diagnosis at this site (Crimi et al., 2019; Suazo et al., 2015b).

The transmission of HSV infection usually requires intimate contact with an infected person, and up to 40 close-contact interactions have been estimated to be required to transmit HSV-2 in genital infections (Wald et al., 2006; Suazo et al., 2015b). Infection may be transmitted by direct contact with infected tissues or through the presence of the virus in the secretions of an infected individual in contact with the mucosae or eroded skin of a healthy person (Suazo et al., 2015b; Fatahzadeh and Schwartz, 2007).

It is noteworthy that during herpetic recurrences, only 20–50% or 80–90% of the individuals infected with HSV-1 or HSV-2, respectively, manifest herpes infection-associated clinical symptoms (Álvarez et al., 2020; Johnston and Corey, 2015). Nevertheless, both symptomatic and asymptomatic individuals may shed HSV from infected tissues (Suazo et al., 2015b; Fatahzadeh and Schwartz, 2007). Indeed, HSV-infected persons shed virus from the mouth up to 3–5 days after oral lesions are resolved, whereas viral shedding after genital infections is highest in the first 6–12 months after infection. However, virus shedding can persist for years, thus contributing to the silent infection of other individuals (Gupta et al., 2007; Fatahzadeh and Schwartz, 2007). Additionally, asymptomatic persons may shed virus and transmit it through respiratory droplets or through mucocutaneous secretions in the absence of clinical manifestations (Fatahzadeh and Schwartz, 2007). Importantly, a study estimated that asymptomatic individuals shed HSV-2 3–5% of the days when assessed by cell culture and up to 28% of days when tested by PCR (Wald et al., 1997).

Skin infections

Two of the most common skin-related clinical manifestations caused by herpes simplex viruses are herpes labialis and herpetic gingivostomatitis. Herpes labialis is commonly caused by HSV-1, but HSV-2 infection may also be a cause (Lafferty et al., 1987). Herpes labialis is characterized by the development of a rash in the skin or mucous membranes, primarily in the lips, which causes erythema and blisters frequently accompanied by a burning sensation of pain (Opstelten et al., 2008). A significant number of patients with this type of clinical manifestation elicited by HSV-1 have recurrences, which may repeat more than six times in a year (Celik et al., 2013). Recurrences may last up to 10 days if no treatment is taken (Arduino and Porter, 2008; Álvarez et al., 2020; Fig. 1).

Herpetic gingivostomatitis is commonly observed in children and young adults and consists of painful oral lesions in the buccal and gingival mucosa and the tongue (Amir, 2001). In children, most primary infections with HSV cause clinical manifestations that are either mild or asymptomatic (Arduino and Porter, 2008), and only 13–30% of the infected children manifest gingivostomatitis (Amir, 2001). The disease is mainly self-limiting (Arduino and Porter, 2008). Although most of the cases are caused by HSV-1, some cases due to HSV-2 have been reported (George and Anil, 2014; Fig. 1).

Herpes simplex viruses can also elicit other skin-related diseases, such as Eczema herpeticum (EC), which is characterized by disseminated dome-shaped vesicle eruptions through the upper body, fever, malaise, and lymphadenopathy (Wollenberg, 2012; Fig. 1). Noteworthy, herpes simplex virus-elicited Eczema herpeticum shares some clinical features with shingles produced by the varicella-zoster virus (HHV-3, VZV), and hence may be occasionally mistakenly diagnosed (Freer and Pistello, 2018). Children with severe atopic dermatitis have been reported to be at higher risk of recurrent HSV, suffering EC (Darji et al., 2017). Somewhat related to EC is herpes gladiatorum, which has been defined as herpetic skin lesions produced by HSV in athletes that practice wrestling activities. Infection of the skin in these individuals likely occurs because of skin abrasion or skin breakdown due to wrestling, with the virus from contaminated saliva from the adversary entering in contact with the skin (Anderson, 2003; Anderson, 2008; Johnson, 2004; Fig. 1). On the other hand, another manifestation, herpetic whitlow, is characterized by the formation of a single herpetic vesicle or cluster of vesicles, usually located in the terminal phalanx of the thumb, index, or long finger near the nail and is associated with throbbing pain (Rubright and Shafritz, 2011; Fig. 1).

Ocular infections

Ocular infections by herpes simplex viruses are the most common cause of infectious blindness in developed countries, with herpetic keratitis being estimated to be the cause of approximately 40,000 annual new cases of blindness or severe visual impairment worldwide (Farooq and Shukla, 2012). Herpetic keratitis may result as a consequence of epithelial keratitis or stromal keratitis, compromising the cornea (Rowe et al., 2013). Importantly, this type of clinical manifestation by HSV may occur recurrently, leading in the long-term to irreversible damage of the cornea and the need for cornea transplant (Rowe et al., 2013). Although HSV-1 is more frequently isolated from the eye than HSV-2, a study analyzing corneal buttons of patients with herpes stromal keratitis found that this disease can be caused by either HSV-1 or HSV-2, and in one case, a mixed infection was found (van Gelderen et al., 2000). Ocular infections with HSV-1 may also lead to blepharitis, conjunctivitis, or iridocyclitis (Liesegang, 2001). HSVs have also been reported to cause uveitis (Inoda et al., 2001; Chan and Chee, 2019). Additionally, HSV-2 has been reported to cause retinitis and acute necrotic retinitis (Rowe et al., 2013; Itoh et al., 2000; Grose, 2012; Fig. 1).

Central nervous system infections

Herpes simplex viruses have tropisms for neurons where they can establish latency and from where they can reactivate to produce recurrences (Duarte et al., 2019). Besides infecting neurons of the trigeminal ganglia in the facial area and dorsal root ganglia of the sacral area, HSVs can also reach the brain where they can establish asymptomatic infections with potential contributions to neurodegenerative diseases (Duarte et al., 2019, 2021). However, HSVs can also elicit acute encephalitis with lifelong detrimental effects over this tissue (Duarte et al., 2019; Fig. 1).

Individuals suffering herpetic encephalitis often display lifelong sequelae, despite antiviral treatment, such as with acyclovir (Duarte et al., 2019). Furthermore, neonatal herpetic encephalitis is associated with high morbidity and mortality, with untreated infections reaching case-mortality rates of 60% (Corey and Wald, 2009). Most of the infections in neonates occur due to exposure to virus that was shed by the mother in the genital tract during childbirth (Corey and Wald, 2009). On the other hand, most of the cases in children and young adults have been associated with viral reactivations of HSV-1, likely derived from previously infected neurons (Steiner and Benninger, 2013).

While HSV-1 is the leading cause of sporadic viral encephalitis in adults (Duarte et al., 2019), HSV-2 infections of the brain in neonates are more common than HSV-1 (Kleinschmidt-DeMasters and Gilden, 2001). Encephalitis due to HSV-2 in adults also occurs and has been reported to be the cause of 6% of frontal-temporal encephalitis in immunocompetent patients. It is usually associated with aseptic meningitis, acute and subacute myelitis, and chronic meningitis, among others (Kleinschmidt-DeMasters and Gilden, 2001). This disease is usually characterized as a necrotizing inflammatory process and frequently affects the cortex and underlying white matter of the temporal lobe (Hauer et al., 2019). A comparative analysis has shown that, while HSV-1 mostly elicits intracerebral hemorrhage, cases with infarction were usually associated with HSV-2 infections (Hauer et al., 2019). Brain damage in HSV encephalitis seems to be mainly provoked by neuronal cell death via apoptosis or necrosis, and it is associated with the insular cortex of cerebral hemispheres and with the temporal and front lobes of the brain (Bradshaw and Venkatesan, 2016).

On the other hand, central nervous system (CNS) infection with HSVs can elicit Mollaret's syndrome, which is characterized by aseptic inflammation of the meninges consisting of leukocyte infiltration and the presence of Mollaret's cells in this tissue (Suazo et al., 2015b; Shalabi and Whitley, 2006; Poulikakos et al., 2010; Farazmand et al., 2011). It has been described that one-third of the individuals that undergo recurrent meningitis suffer spasm episodes, cranial nerve paralysis, diplopia, hallucinations, pathological reflexes, and even coma (Suazo et al., 2015b; Shalabi and Whitley, 2006; Poulikakos et al., 2010; Sato et al., 2005; Fig. 1).

Genital infections

Herpes genitalis or genital herpes is a common, sexually transmitted disease. Although it is mostly associated with HSV-2, it is also caused by HSV-1, which is frequently detected during primary genital herpetic infections (Groves, 2016; Löwhagen et al., 2002). Indeed, in the United States, genital herpes caused by HSV-1 is more common than HSV-2 among young women (Bernstein et al., 2013). Nevertheless, HSV-1 seemingly recurs less often from the dorsal root ganglia than HSV-2. Hence, the latter is more frequently found in recurrent herpetic lesions in this tissue, up to 4–5 times a year, and less than 10% of the recurrences are caused by HSV-1 (Retamal-Díaz et al., 2015; Suazo et al., 2015b; Lafferty et al., 1987; Solomon et al., 2003). The differential reactivation of HSV-1 and HSV-2 from neurons linked to the genital area may be related to the preference of these viruses for A5 and KH10 positive neurons, respectively (Retamal-Díaz et al., 2015). Clinical manifestations by HSVs in this area include single or clustered vesicles in the genitalia, perineum, buttocks, upper thighs, or perianal areas (Groves, 2016). Malaise, fever, or localized adenopathy may also occur during primary genital herpetic infection, while recurrences in this area usually cause milder symptoms (Groves, 2016; Fig. 1).

HSV-2 and HIV

Over the last decades, an important association has been made between HSV-2 and the human immunodeficiency virus (HIV; Suazo et al., 2015b; Looker et al., 2017a). Notably, it has been found that infection with HSV-2 increases up to three-fold the risk of acquiring HIV (Freeman et al., 2006). Furthermore, there is evidence that an association between these viruses is somewhat reciprocal, given that infection with HIV also increases the likelihood of HSV-2 reactivations (Mayaud et al., 2008).

The mechanisms by which these two viral infections are related are diverse. While some studies have reported that infections with HSV-2 increase HIV transmission due to genital ulcerations elicited by the former (Corey et al., 2004), other studies suggest that the cytokines secreted by HSV-2-infected DCs contribute to HIV replication (Stefanidou et al., 2013). Additionally, microlesions provoked by HSV-2 may expose HIV to target immune cells that reside in the infection site, such as dendritic cells, macrophages, and Langerhans cells (Duluc et al., 2013). Furthermore, some studies have shown that in HSV-2-infected tissues, receptors for HIV in target cells, such as DC-SIGN and CCR5, are upregulated in CD4⁺ T cells and DCs, respectively, which are present at higher amounts (Johnson et al., 2011; Rebbapragada et al., 2007). In sum, infections with HSV-2 may have a significant impact on the HIV epidemic, and thus, preventing HSV-2 infection may work as an indirect strategy for limiting the HIV pandemic.

Vaccine research and treatment of herpes simplex viruses

Vaccine development against HSVs

There are currently no vaccines available against HSVs. However, there are numerous ongoing studies and vaccine candidates that are being tested in different pre-clinical and clinical settings (Johnston et al., 2016). These vaccines are being developed to prevent or treat (therapeutic vaccines) HSV infections. While most of these studies have prioritized HSV-2 vaccine development over HSV-1, nevertheless, given the high homology and similarity between these two viruses, some HSV-2 vaccine candidates may also prevent HSV-1 infection as observed in animal models and clinical trials (Johnston et al., 2016; Petro et al., 2015; Belshe et al., 2012).

At present, most vaccine candidates have considered targeting the process of HSV entry into target cells through the induction of neutralizing antibodies, yet some clinical studies suggest that these antibodies may not correlate with protection against infection by both HSVs, and their related clinical manifestations (Petro et al., 2015; Belshe et al., 2012; Burn et al., 2018; Chung and Sen, 2012). The different approaches that have been tested include attenuated vaccines against HSVs, replication-limited virus-based vaccines, viral vectors, DNA vaccines, inactivated vaccines, and subunit vaccines, among others (Chung and Sen, 2012; Retamal-Díaz et al., 2016).

Inactivated virus-based vaccines have been tested as a strategy for preventing clinical manifestations by HSV in humans, yet they have been shown to fail in preventing infection and disease (Skinner et al., 1997). For instance, a vaccine candidate that was composed of fractions of HSV-1 proteins obtained from inactivated HSV-1-infected cell lysates was able to induce the stimulation of neutralizing antibodies and lymphocytes, but the reduction in HSV recurrence in patients that were previously infected failed to reach statistical significance when tested in a clinical trial (Skinner et al., 1997; Table 1).

Subunit vaccine strategies are among the most tested approaches against HSV-1 and HSV-2 in human clinical trials (Cairns et al., 2014). Most of these studies were initiated in guinea pigs, in which combinations of purified HSV-1 glycoproteins reduced the morbidity associated with infection after viral challenge with HSV-2, and elicited protection against secondary central nervous system symptoms (Meignier et al., 1987). Later, it was also shown that an HSV-2 glycoprotein D (gD) subunit vaccine protected against both HSV-1 and HSV-2 in the guinea pig model, which promoted clinical trials using this approach (Bourne et al., 2003). A gD2-based subunit vaccine candidate with alum/MPL as an adjuvant was tested in large clinical trials enrolling HSV-1 and HSV-2 seronegative women; regrettably this approach only partially protected against HSV infection (58% protection for HSV-1 genital disease, 35% for HSV-1 infection and no efficacy for HSV-2 infection; Belshe et al., 2012). Surprisingly, high antibody titers against gD-2, induced by the vaccine were found (Belshe et al., 2014; ClinicalTrials.gov Identifier: NCT00057330). Other efforts have also been invested in developing HSV-2 gD-based subunit candidate vaccines in the past and failed at eliciting significant efficacy in clinical trials (Straus et al., 1997, 1994). For instance, although it was shown that a HSV-2 gD- and gB-adjuvanted vaccine candidate with MF59 was immunogenic, it did not prevent recurrent genital herpes and only had mild reactogenicity in humans (Corey et al., 1999; Table 1).

Table 1 Vaccine research on herpes simplex viruses.

<i>Vaccine strategy</i>	<i>Outcome</i>	<i>References</i>
Inactivated virus-based vaccines		
Fractions of HSV-1 proteins	Induced neutralizing antibodies and lymphocytes. Reduced viral recurrence in patients. However, in clinical trials this reduction was not statistically significant.	Skinner et al. (1997)
Subunit-based vaccines		
Mix of purified HSV-1 glycoproteins	Elicited reduced morbidity and protection against secondary central nervous system symptoms upon HSV-2 infection in guinea pigs.	Meignier et al. (1987)
Adjuvanted HSV-2 gD and gB proteins	Immunogenic but results showed no prevention of recurrent genital herpes and only mild reactogenicity in humans.	Corey et al. (1999)
gD-Alum/3-deacylated form of Monophosphoryl Lipid A (MPL)	Phase 3 completed. Results showed partial protection against HSV-1 and no protection against HSV-2 infection.	Belshe et al. (2012) ; Belshe et al. (2014); NCT00057330
HSV-2 recombinant proteins ICP4, gD and matrix M2	Phase 2 completed. No results posted to date.	NCT02114060
32 synthetic 35mer HSV-2 peptides and QS-21 Stimulon	Phase 2 completed. No results posted to date.	NCT01687595
Attenuated virus-based vaccines		
HSV-2 G strain with deletions in both copies of the gamma-34.5 gene and the <i>UL55</i> and <i>UL56</i> open reading frames	Impaired viral recurrences in guinea pigs.	Spector et al. (1998)
HSV-2 with the gene encoding gH (<i>UL22</i>) deleted	Reduces viral replication and the recurrence of genital lesions in guinea pigs, but failed to confer significant protection when tested in humans.	Mc Lean et al. (1994); Aurelian (2004)
HSV-1 with the <i>ICP0</i> open reading frame replaced with a gene encoding a tetracycline repressor and a mutation that replaces the <i>UL9</i> gene with an extra copy of gD (<i>US6</i>)	Reduces latent infections and protects against primary and recurrent HSV-2 infections in guinea pigs.	Brans et al. (2009)
HSV-1 with the gene encoding gK (<i>UL53</i>) deleted	Prevents virus entry into distal axons of ganglionic neurons and protects against intravaginal challenge with HSV-1 and HSV-2 in mice.	Iyer et al. (2013)
HSV-2 with gD deletion in the viral genome complemented in trans with the corresponding glycoprotein	Effective against HSV-1 and HSV-2 genital and skin infections. Prevents the establishment of viral latency.	Petro et al. (2015)
HSV-2 mutant with deletions in the genes encoding for <i>UL5</i> and <i>UL29</i>	Phase 1 completed. No results posted to date.	NCT02571166
Viral vector-based vaccines		
Vaccinia virus expressing HSV-1 gD	Reduces the severity of HSV-1 and HSV-2 infections in a murine model.	Rooney et al. (1991)
Defective adenovirus capable of expressing gD2	Higher protection against vaginal challenge in mice when compared to an FI-HSV2 vaccine.	Liu et al. (2017)
DNA-based vaccines		
DNA encoding HSV-2 gD (<i>US6</i> gene)	Proven to be safe and induce gD-specific cytotoxic T-lymphocyte and lymphoproliferation responses in a phase I clinical trial.	Cattamanchi et al. (2008)
Plasmid DNA vaccine encoding two HSV-2 proteins	Phase 2 completed. No results posted to date.	NCT02837575
Plasmid DNA vaccine encoding one HSV-2 protein	Phase 2 completed. No results posted to date.	NCT02030301
DNA vaccine encoding HSV-2 ICP0, ICP4, ICP22 and ICP27 antigens	Phase 1 completed. No results posted to date.	NCT00274300

Other HSV subunit vaccine candidates that were assessed in clinical trials include a vaccine comprised of the HSV-2 viral proteins ICP4 and gD2 combined with the matrix M2 adjuvant that was tested in a phase II clinical trial ([ClinicalTrials.gov](#) Identifier: NCT02114060), and a peptide-based vaccine candidate composed of 32 HSV-2 synthetic peptides 35mer-long mixed with the QS-21 adjuvant also tested in a phase II clinical trial ([ClinicalTrials.gov](#) Identifier: NCT01687595). However, to our knowledge, the results of these clinical studies have not been reported or published to date (Table 1).

On the other hand, numerous attenuated vaccine candidates against HSV have been developed and tested. One such attenuated vaccine candidate is RAV 9395, which is an HSV-2 G-strain based virus that has deletions in both copies of the gene encoding the viral protein γ 34.5, and the open reading frames of the *UL55* and *UL56* genes. This virus was tested in guinea pigs and was shown to impair viral recurrences (Spector et al., 1998). Furthermore, a vaccine candidate based on HSV-2 with a deletion in the gene that encodes the gH protein was shown to reduce viral replication and the recurrence of genital lesions in guinea pigs, yet it failed to show efficacy when tested therapeutically in humans (Mc Lean et al., 1994; Aurelian, 2004). Another vaccine candidate with replication-limited properties is an HSV-2 mutant with deletions in the genes encoding for *UL5* and *UL29*, which was proven to be safe, protective, and immunogenic when tested in mice and guinea pigs (Hoshino et al., 2009). A vaccine candidate with mutations in these two genes has completed a phase I clinical trial, yet the results have not been posted to date ([ClinicalTrials.gov](#) Identifier: NCT02571166). This vaccine candidate is currently being tested in a phase II clinical trial ([ClinicalTrials.gov](#) Identifier:

NCT04222985; Kim and Lee, 2020). T-REx™ consists of a replication-defective HSV-1 recombinant vaccine reportedly reduces latent infections and produce a protective immune response against both, primary and recurrent HSV-2 infections in guinea pigs (Brans et al., 2009). This vaccine replaces the open reading frame of *ICP0* with a gene encoding for a tetracycline repressor and also has another mutation that replaces the gene encoding for *UL9* with an extra copy of the *US6* gene that encodes for gD (Brans et al., 2009)). There is also evidence that the use of an HSV-1 mutant virus with a deletion of the gene encoding glycoprotein K (gK), which prevents the virus from entering distal axons of ganglionic neurons, protects against intravaginal challenge with the HSV-1 strain McKrae and HSV-2 strain G in mice (Iyer et al., 2013). On the other hand, there is also mounting evidence that a live-attenuated HSV-2 vaccine candidate with a deletion in glycoprotein D, complemented with the corresponding glycoprotein in *trans*, that experiences a single round of replication may be effective against both HSV-1 and HSV-2 genital and skin infections (Petro et al., 2015, 2016; Burn et al., 2018, 2018). Surprisingly, in the mouse model, this approach prevented the establishment of viral latency (Petro et al., 2015; Table 1).

Interestingly, the different outcomes that each HSV mutant yield, particularly at mounting or not protective immune responses may be related to the interaction of these mutant viruses with DCs. Indeed, distinctive mutations in HSV seem to modulate differently the function of these cells, which are key for establishing an effective antiviral immune response (Retamal-Díaz et al., 2017a,b; Table 1).

Additionally, viral vector-based vaccine candidates have also been developed and tested against HSV. For instance, a recombinant vaccinia virus expressing HSV-1 gD has been reported to reduce the severity of HSV-1 and HSV-2 infections in a murine model (Rooney et al., 1991). Also, a vaccine candidate based on adenovirus that consists of a replication-defective adenovirus recombinant for HSV-2 gD (rAd-gD2) has been tested and reported to provide higher protection against vaginal challenge than formaldehyde-inactivated HSV-2 (FI-HSV2) in mice (Liu et al., 2017; Table 1).

DNA vaccines have also been tested as a strategy for developing vaccines against HSV (Cattamanchi et al., 2008; Chung and Sen, 2012). Importantly, an HSV-2 gD-based DNA vaccine was reported to be safe and induce gD-specific cytotoxic T-lymphocyte and lymphoproliferation responses in a phase I clinical trial (Cattamanchi et al., 2008). On the other hand, the therapeutic pPJV7630 HSV-2 DNA vaccine encoding HSV-2 ICP0, ICP4, ICP22 and ICP27 antigens, completed a phase I of clinical trial with no results posted to the date to our knowledge (Stanberry and Rosenthal, 2005) (ClinicalTrials.gov Identifier: NCT00274300, ClinicalTrials.gov Identifier: NCT00310271). Additionally, two plasmid DNA vaccines encoding one or two HSV-2 proteins have completed phase II clinical trials; however, these studies have not reported their results yet (ClinicalTrials.gov Identifier: NCT02030301, ClinicalTrials.gov Identifier: NCT02837575; Table 1).

Some of the HSV vaccine candidates discussed above and currently undergoing advanced stages of testing in animal models or clinical trials are summarized in Table 1.

Current treatments and drugs for HSV infections

At present, several antiviral drugs are available for treating HSV infections and somewhat preventing recurrent, as well as the prolongation of herpetic lesions. The most commonly known and used are acyclovir (ACV), valacyclovir, and penciclovir, which act over the viral polymerase and hamper genome replication of both types of HSVs (Kukhanova et al. (2014)). However, these drugs are somewhat ineffective for some clinical manifestations, such as treating skin lesions (discussed below), and HSV variants that are resistant to these drugs frequently emerge in immunosuppressed individuals (up to 3.5–10% of immunosuppressed individuals), as well as immunocompetent individuals (1% of cases). Therefore, there is an urgent need in finding more effective antivirals and novel approaches for these drug-resistant variants (Reusser, 1996). Noteworthy, at present, there are numerous synthetic and botanical compounds being assessed as potential new antivirals against HSVs (Álvarez et al., 2020; Akram et al., 2018; Gonzalez et al., 2018).

Common first-line drugs used against HSVs

The most common drugs available against HSVs are nucleoside and nucleotide analogs. Acyclovir is an acyclic guanosine nucleoside and is currently the most widely used compound to treat HSV infections around the globe (Hassan et al., 2015; Álvarez et al., 2020). ACV is mostly safe, well-tolerated, and low cost (Hassan et al., 2015). However, this drug has some limitations, as the absorption of ACV through the oral route nears 15–30%, and thus, requires frequent administration (every 4 h). Therefore, the dosing consists in considerable amounts of the drug being taken (Bryson et al., 1983; Bean, 1992; Cortesi and Esposito, 2008). For skin lesions, ACV has been shown to reduce the healing process by only approximately two days if taken as soon as the first clinical symptoms arise, of an estimated total of 8 days (Bean, 1992; Spruance et al., 1990). For ACV to be effective, the drug needs to be phosphorylated to its active form, which is acyclovir triphosphate (Reusser, 1996; De Clercq, 2013). The first phosphorylation is carried out by the viral thymidine kinase (TK, *UL23* gene), and subsequent phosphorylations by cellular kinases (Kukhanova et al., 2014; Reusser, 1996; Table 2).

The nucleic acid analogs valacyclovir, penciclovir and famciclovir are also frequently used to treat HSVs infections. Similar to ACV, these compounds also reduce the duration of the herpetic skin lesions in approximately 1–3 days, as compared to the untreated groups (Emmert, 2000). Valacyclovir is an L-valine ester of acyclovir developed to increase its bioavailability and has an increased absorption at the intestinal level, equivalent to 54% (Soul-Lawton et al., 1995). Penciclovir is more rapidly

Table 2 Current strategies available and under research for treating HSV infection.

Compound	Characteristics	Virus tested	Development stage	Mechanism of action	Reference
Acyclovir	Nucleoside Analogue	HSV-1 and HSV-2	FDA and EMA approved	Inhibitor of viral DNA replication	Bryson et al. (1983) Kukhanova et al. (2014)
Valacyclovir	Nucleoside Analogue	HSV-1 and HSV-2	FDA and EMA approved	Inhibitor of viral DNA replication	Kukhanova et al. (2014); Schuster et al. (2016)
Penciclovir	Nucleoside Analogue	HSV-1 and HSV-2	FDA and EMA approved	Inhibitor of viral DNA replication	Kukhanova et al. (2014); Meira et al. (2019)
Famciclovir	Nucleoside Analogue	HSV-1 and HSV-2	FDA and EMA approved	Inhibitor of viral DNA replication	Emmert (2000); Mondal (2007)
Ganciclovir	Nucleoside Analogue	HSV-1 and HSV-2	FDA and EMA approved	Inhibitor of viral DNA replication	Chou and Hong (2014); Al-Badr and Ajarim (2018)
Cidofovir	Nucleotide Analogue	HSV-1 and HSV-2	FDA and EMA approved	Inhibitor of viral DNA replication	Lea and Bryson (1996); Chilukuri and Rosen (2003)
Brincidofovir	Nucleotide Analogue	HSV-1 and HSV-2	Under FDA Review	Inhibitor of viral DNA replication	Hostettler (2009); Lee et al. (2018)
Pritelivir	Helicase-Primase Inhibitor	HSV-1 and HSV-2	In Clinical Trials	Inhibitor of viral DNA replication	Wald et al. (2014); Poole and James (2018)
Amenamivir	Helicase-Primase Inhibitor	HSV-1 and HSV-2	In Clinical Trials	Inhibitor of viral DNA replication	Kawashima et al. (2017); Poole and James (2018)
Docosanol	Saturated Alcohol	HSV-1 and HSV-2	FDA and EMA approved	Inhibitor of Entry	Treister and Woo (2010); De Clercq and Li (2016)
Idoxuridine	Deoxyuridine Analogue	HSV-1	FDA and EMA approved	Inhibitor of viral DNA replication	Wilhelmus (2015); De Clercq and Li (2016)
Vidarabine	Nucleoside Analogue	HSV-1 and HSV-2	FDA and EMA approved	Inhibitor of viral DNA replication	Chou and Hong (2014); De Clercq and Li (2016)
Trifluridine	Nucleoside Analogue	HSV-1 and HSV-2	FDA and EMA approved	Inhibitor of viral DNA replication	Wilhelmus (2015); De Clercq and Li (2016)
Nelfinavir mesylate	HIV-1 Protease Inhibitor	HSV-1	In use for HIV-1. In clinical trials for HSV treatment	Inhibit the maturation and export of viral particles	Kalu et al. (2014)
Benzalkonium Chloride	Alkylamine	HSV-2	Non reported	Virucidal	Bélec et al. (2000)
<i>Aglaia odorata</i>	Unknown	HSV-1	Evaluated in animals	Inhibition after viral attachment HSV-1	Lipipun et al. (2003)
<i>Moringa oleifera</i>	Unknown	HSV-1	Evaluated in animals	Inhibition after viral attachment HSV-1	Lipipun et al. (2003)
<i>Ventilago denticulata</i>	Unknown	HSV-1	Evaluated in animals	Inhibition after viral attachment HSV-1	Lipipun et al. (2003)
<i>Alternanthera philoxeroides</i>	Chikusetsusaponin IV	HSV-1 and HSV-2	Evaluated in animals	Virucidal	Rattanathongkom et al. (2009)
<i>Melia azedarach</i>	Meliacine (Glycopeptide)	HSV-1 and HSV-2	Evaluated in animals	Unknown or not reported	Petrera and Coto (2009)
<i>Griffithsia</i> sp.	Griffithsin	HSV-2	Evaluated in animals	Inhibition of viral binding, inhibition of viral entry	Derby et al. (2018); Nixon et al. (2013)

phosphorylated than ACV and has a higher half-life (Soul-Lawton et al., 1995). While the half-life of ACV against HSV-1 is 0.7 h and against HSV-2 1 h, the half-life of penciclovir for HSV-1 and HSV-2 is 10 and 20 h, respectively (Hodge and Perkins, 1989; Lubber and Flaherty, 1996). Lastly, famciclovir is a prodrug of penciclovir that has been shown to have higher oral bioavailability than penciclovir, approximately 25% vs. 3% for the latter when tested in mice (Hodge et al., 1989; Sutton and Kern, 1993). It is noteworthy to note that resistance to each of these four first-line drugs has been described. Therefore, there is a need for developing new antiviral strategies to treat these drug-resistant variants (Reusser, 1996; Table 2).

Other drugs used to treat HSV skin lesions include a combination of acyclovir (50 mg) with hydrocortisone (10 mg) for topical use, or alternatively docosanol, which consists of an hydrophobic linear chain compound with an alcohol group at one of its ends that is formulated at 10% as a topical cream. Other options, yet seemingly discontinued, are a zinc oxide-based cream that is used to treat HSV-1 skin lesions, and benzalkonium chloride intended for HSV-2 skin lesions (Strand et al., 2012; Woo and Challacombe, 2007; Bélec et al., 2000; Godfrey et al., 2001; Table 2).

On the other hand, trifluridine, a nucleotide analog, is primarily used to treat herpetic keratitis (Chou and Hong, 2014). However, some severe local side effects have been described for this compound (Chou and Hong, 2014; Álvarez et al., 2020). Finally, the anti-HSV compounds idoxuridine and vidarabine, two nucleoside analogs that were the first antivirals identified against HSVs, have been discontinued given that more effective treatments are currently available to treat HSV infections (Álvarez et al., 2020; Table 2).

Second-line drugs against HSVs

Other nucleotide and nucleoside drugs that are considered second-line drugs have emerged in the last decades for treating HSV infections. For instance, ganciclovir is a nucleic acid analog that has antiviral activity against both HSV-1 and HSV-2 (Smee et al., 1983; Chou and Hong, 2014; Matthews and Boehme, 1988). Additionally, cidofovir, an acyclic nucleotide analog, also has antiviral effects against acyclovir-resistant HSV-1 and HSV-2 isolates (Chilukuri and Rosen, 2003). Like acyclovir, this compound also interferes with the activity of the viral DNA polymerase, and once transformed into its nucleotidic form, it has a much higher affinity towards the viral DNA polymerase than the host DNA polymerase. Hence, the inhibition of viral genome replication is more effective than with acyclovir (Ho et al., 1992). Nevertheless, these drugs have been reported to cause some severe side effects such as nephrotoxicity, altered mental status, abnormal levels of liver enzymes in serum, acute tubular necrosis, among others (Arvin et al., 2007; Sauerbrei, 2016; Table 2).

New drugs against HSVs

Currently, numerous new anti-herpetic drugs are being tested in animal models or clinical trials. For instance, 7-chloro-1,3-dihydroxyacridone and 1,3,7-trihydroxyacridon, two DNA topoisomerase II catalytic inhibitors, have been reported to inhibit HSV replication *in vitro* and cell-based experiments (Akanitapichat et al., 2000). Additionally, 5-chloro-1,3-dihydroxyacridone was found to inhibit the cleavage and packaging of viral DNA into capsids, interfering with viral maturation, which produced atypical B-type capsids (B-type capsids are explained in the virus egress section). Interestingly, this compound did not display DNA topoisomerase II inhibitory activity (Akanitapichat and Bastow, 2002; Álvarez et al., 2020; Table 2).

Additionally, new chemical compounds are being assessed in clinical trials as anti-herpetic drugs. For example, brincidofovir an acyclic nucleotide phosphonate has been shown to act as a substrate inhibitor of the viral DNA polymerase *in vitro* studies (Hostetler, 2009; Álvarez et al., 2020). On the other hand, amenamevir and pritelivir are two viral helicase inhibitors that target the viral DNA helicase/primase complex (H/P; Kleymann et al., 2002; Poole and James, 2018). To our knowledge, the results of these clinical trials have not been published yet. Finally, a mesylate salt, nelfinavir mesylate, which is an HIV-1 protease inhibitor, has been reported to have antiviral activity against HSV-1 and inhibit the maturation and export of viral particles (Markowitz et al., 1998; Kalu et al., 2014). This compound is being assessed in a clinical trial to treat Kaposi's sarcoma, but its potential effect against HSV-1 and HSV-2 is also considered a goal in this study (ClinicalTrials.gov Identifier: NCT03077451; Table 2).

On the other hand, many botanical compounds have been reported to have antiviral activity against HSVs, both *in vitro* and animal models. For a comprehensive review on this subject, we suggest referring to Álvarez et al., which revises the antiviral activity of compounds derived from plants, algae, and fungus, among others (Álvarez et al., 2020). Some of the studies reporting such activities are discussed below.

Plant-derived compounds with antiviral effects against HSVs in mice infected with HSV-1 have been reported for *A. odorata*, *M. oleifera*, and *V. denticulata*, which, combined with ACV diminished the development and progression of skin lesions and increased the mean survival time of the animals (Lipipun et al., 2003). Another study reported that an *Alternanthera philoxeroides* extract, namely Chikusetsusaponin IV has antiviral activity against HSV-2 genital infection in mice up to 7 days post-infection (Rattanathongkom et al., 2009). A glycopeptide from *Melia azedarach* glycopeptide has also been reported to have antiviral properties against HSV-2 infections when tested in a mouse model (Petrera and Coto, 2009; Table 2).

Algae extracts and compounds with antiviral potential against HSV include extracts from the algae species *Griffithsia* sp., which was shown to have anti-HSV-2 activity in a murine model, likely through blocking the infection process and cell-to-cell spread of this virus (Nixon et al., 2013). *Griffithsia* sp. extracts have since then been further characterized and tested in different animal models (Derby et al., 2018; Lee, 2019). Extracts of the algae *Symphyocladia latiuscula* have been shown to block viral plaque-forming units *in vitro*, and skin biopsies obtained from HSV-1-infected animals also displayed lesser virus than the controls (Park et al., 2005).

Moreover, recently it was described that algae extracts from *Macrocystis pyrifera* and *Durvillaea antarctica* display potent antiviral activity against acyclovir-sensitive and acyclovir-resistant HSV-1 and HSV-2 and reduced the duration and severity of HSV-1 skin lesions in mice, more than acyclovir (Castillo et al., 2020). Finally, the algae species *L. dendroidea*, *U. fasciata*, *C. decorticatum*, *S. zonale*, *S. cymosum*, *C. acicularis* and *P. capitatus* of the Brazilian coast have been shown to have strong antiviral effects against HSVs, both sensitive and resistant to acyclovir in *in vitro* studies (Soares et al., 2012; Table 2).

Interestingly, fungus-derived compounds have also been identified as potential novel antiviral treatment against HSVs. For instance, *Agaricus brasiliensis* was shown to reduce the severity of HSV-2 disease in a murine genital infection model (Cardozo et al., 2013). Also, mice treated with a protein isolated from *Grifola frondosa* reduced blepharitis, vascularization, and stromal disease, in addition to reduced viral replication in the eye when applied topically at this site (Gu et al., 2007). Interestingly, the *Rozites caperata* RC28 protein has also been shown to reduce the severity of stromal keratitis (Agrawal and Jha, 2020; Table 2).

HSV replication cycle

HSV structure

Herpes simplex viruses share common features with other viruses of the *Herpesviridae* family, and more notoriously with those in the *Alphaherpesvirinae* subfamily (Boehmer and Nimonkar, 2003). These viruses are characterized by four primary features starting from the exterior to their core: namely, they have an envelope with glycoproteins, a tegument, a capsid, and at the center the viral genome (Ibáñez et al., 2018; Fig. 2).

The envelope of HSV virions is composed of a lipid bilayer, which holds numerous of the eleven viral glycoproteins encoded in the viral genome (Suazo et al., 2015a; Fig. 2). These glycoproteins participate in different molecular processes throughout the viral life cycle, such as binding to the cell surface and entry of virion components into the cytoplasm of target cells (described later in this chapter), as well as the exit of infectious particles (Ibáñez et al., 2018). The tegument layer of the virion is composed of a set of approximately 20 different viral proteins (Vittone et al., 2005). The tegument proteins of the virus play relevant roles in disrupting the early host antiviral response, they enhance viral gene transcription, and aid in the transport of the viral capsids towards and out of the nucleus, among others (Ibáñez et al., 2018).

Electron microscopy analyses show that the viral capsids of herpes simplex viruses have an icosahedral shape and measure around 125 nm of diameter (Brown and Newcomb, 2011). Recently, cryo-electron tomography has brought exquisite detail to the structure of the viral capsid revealing details of the portal through which viral DNA is injected into the nucleus of the cells, among others (Cardone et al., 2007; Rochat et al., 2014). The capsid contains a single copy of a linear double-stranded DNA genome of more-less 150 kbp, which encodes approximately 80 genes and has a high GC content (Kieff et al., 1971). The spherical particle in which the tegument and capsid are contained is approximately 186 nm. The overall size of the viral particle, including the extensions of the glycoproteins on the virion surface, nears 225 nm (Grünwald et al., 2003; Fig. 2).

Cell infection

Herpes simplex virus infection of host cells initiates when virions bind to the cell surface, particularly through glycoprotein B (gB) and glycoprotein C (gC) for HSV-1 to heparan-sulfate proteoglycans (HSPGs) on the cell surface. Although gB is required for HSV-2

Fig. 2 HSV structure. From the inside-out, HSV virions are composed of a linear double-stranded DNA (~154 kbp) that encodes approximately 80 genes. The viral genome is contained within an icosahedral capsid that is surrounded by a layer of numerous viral proteins (approximately 20) called the tegument. The tegument in turn is enveloped by a bilayer lipid membrane that holds numerous glycoproteins that extend from the surface of the virion. HSV particles can have a diameter up to 225 nm approximately.

binding at this stage, gC of HSV-2 is unessential at this step (Herold et al., 1991; Gerber et al., 1995; Atanasiu et al., 2010; Satoh et al., 2008). Additionally, it has been reported that gB also binds to the paired immunoglobulin-like type 2 receptor (PILR; Satoh et al., 2008). Interestingly, even though HSPGs are the main target for the binding of HSV virions, some compounds acting as HSPG mimics have antiviral properties and prevent viral adhesion to the cell surface via competitive inhibition (Gangji et al., 2018). After viral binding to the host cell, glycoprotein D (gD) interacts with one of its receptors, which will vary depending on the cell type being infected. In non-immune cells, nectin-1 (HveC) or nectin-2 (HveB) will be preferred as receptors, while in immune cells, the herpes virus entry mediator (HVEM, TNFRSF14) seems to be the main target receptor (Martinez and Spear, 2001; Richart et al., 2003; Whitbeck et al., 1997; Kovacs et al., 2009). It has also been reported that 3-O-sulfated heparan sulfates are gD ligands (Shukla et al., 1999; Fig. 3).

Once gD binds to one of its receptors, it will suffer conformational changes that lead to the activation of the viral gH/gL complex present in the viral envelope (Atanasiu et al., 2010). Afterward, the glycoprotein H/ glycoprotein L (gH/gL) complex will interact with gB causing its activation so that the latter can act as the viral fusion protein (Atanasiu et al., 2010). This will allow the fusion of the cell membrane and virus envelope, and consequently, the entry of viral components into the cell cytoplasm (Atanasiu et al., 2010). Alternatively, HSV virions can enter the host cell via a pH-dependent endocytosis mechanism in some cells, by a

Fig. 3 Replication cycle of herpes simplex viruses. Schematic representations of the lytic infectious cycle of herpes simplex viruses. (A) First, HSV binds to cell surface receptors thanks to its surface glycoproteins. This triggers the fusion of the virus and cellular membranes, or (B) alternatively an endocytic process can occur, which allows the virus and capsids to enter the cell. (C) Once in the cytoplasm, the capsids are generally transported to the outer nuclear membrane through microtubules, where the viral genetic material is delivered into the nucleus through nuclear pores. (D) Some viral proteins within the tegument, such as VP16 (transactivation factor), are translocated to the nucleus of the cell. The viral genome is then transcribed in three consecutive “waves,” with the sequential transcription of alpha, beta and gamma genes. (E) The genome is circularized in the nucleus for its replication which occurs as a rolling-circle. (F) Viral mRNA is exported from the nucleus to the cytoplasm and translated into proteins. The translation of glycoproteins takes place at the rough endoplasmic reticulum (RER), and their glycosylation occurs in the Golgi apparatus. (G) Viral glycoproteins are then exported to the cell surface and later endocytosed in early endosomes. (H) Other viral proteins are translated in free ribosomes in the cytoplasm and some are translocated to subcellular compartments, where needed. (I) Capsid proteins translocate to the nucleus for assembling the viral capsid at this location. (J) The viral genome is inserted into the capsids in the nucleus, which then traverse the nuclear membranes (envelopment and de-envelopment processes) and access the cytoplasm where they acquire additional tegument proteins. (K) Mature capsids are enveloped into endosomes containing the viral glycoproteins, forming virions within exocytic vesicles. (L) These viral particles are then exocytosed to the extracellular space. Alternatively, infection may occur through cell to cell spread (see main text).

phagocytosis-like uptake process or by the independent activation of gH, which promotes virus entry into the cell through acidic endosomes (Yuan et al., 2018; Rahn et al., 2011; Fig. 3).

After virus access to the cytoplasm, the capsids are transported to nuclear pores. Several tegument proteins that are associated with the capsid play important roles at this step (Ibáñez et al., 2018). It has been suggested that VP26, a tegument protein, interacts with dynein by its light chains RP3 and Tctex1 (Douglas et al., 2004). There is also evidence that other tegument proteins, such as VP1/2 and UL37 may interact with dynein or kinesin-1, thus facilitating microtubule-mediated transport (Abaitua et al., 2012). Additionally, simple diffusion of capsids through the cytoplasm has been described to be enough for their accumulation at the nucleus (Garner, 2003). Once the viral capsids reach the nuclear membrane, interactions occur between viral proteins, namely VP1/2 and nucleoporins Nup358 and Nup214, which participate in viral genome delivery into the nucleus (Batterson et al., 1983; Copeland et al., 2009; Ibáñez et al., 2018; Fig. 3).

Modulation of cell viability

HSVs are capable of modulating cell viability differentially depending on the cell type that is infected. Two HSV-1 glycoproteins, namely gI and gD, have been reported as being capable of inhibiting Fas-mediated apoptosis in a neuroblastoma cell line and in Jurkat cells (Zhou et al., 2000; Jerome et al., 2001). As gI is localized at the cell membrane, its mode of interaction might be by signaling via the Fas receptor or antagonizing the activation of caspase-8 (Jerome et al., 2001). It has also been reported that upon HSV infection, the viral proteins ICP6 and ICP10, which are R1 large subunits of a viral ribonucleotide reductase (RR), bind to caspase-8 through specific domains, which leads to the inhibition of apoptosis in human cells induced by TNF- α through the TNF receptor (TNFR1) (Guo et al., 2015b). On the other hand, it has been described that the R1 HSV proteins may inhibit necroptosis of infected human and mouse cells by binding to the host receptor-interacting protein (RIP) 1/3 (Guo et al., 2015a; Huang et al., 2015).

In contrast, HSV induces apoptosis in immune cells. Natural killer cells (NK cells) undergo apoptosis when interacting with HSV-1-infected macrophages expressing Fas/FasL (Iannello et al., 2011). The viability of DCs is also affected by HSV infection (Retamal-Díaz et al., 2016; Jones et al., 2003), yet the specific mechanisms by which HSV induces apoptosis in DCs is somewhat unknown, although some evidence suggests it is mediated by a reduction in the expression of host c-FLIP (Kather et al., 2010; Stefanidou et al., 2013). Furthermore, HSVs induce the apoptosis of T cells by activating caspase-3, -8, and -9, which leads to the apoptosis of these cells (Vanden Oever and Han, 2010).

Genome replication and viral gene transcription

The viral tegument protein VP16 plays an important role in viral gene transcription and viral genome replication. This protein will act as a transactivator, promoting viral gene expression early after infection (Roizman and Zhou, 2015). Once the virion enters the cell, VP16 will translocate from the cytoplasm to the nucleus, where it will bind to the viral genome and facilitate the transcription of viral genes required for virus replication (Roizman and Zhou, 2015). The replication of the genome of HSV requires its circularization in the nucleus (Skaliter and Lehman, 1994) and is copied as a rolling circle, producing concatemers that consist of several copies of the whole genome in a linear form (Skaliter and Lehman, 1994; Fig. 3).

Transcription of HSV genes occurs sequentially, namely in three predominant waves (Kalamvoki and Roizman, 2008). First, a set of genes named immediate-early or alpha genes are transcribed. These genes mostly encode for products with functions related to the impairment of the host immediate antiviral response and proteins that act as transcription factors that promote the transcription of a subsequent set of genes termed early or beta genes (Silva et al., 2012; Ibáñez et al., 2018; Tognarelli et al., 2019). The products of these later transcripts are involved in promoting the replication of viral genomes and additional transcription factors that mediate the transcription of a later set of viral genes (Ibáñez et al., 2018). Late genes, sometimes separated into late early or gamma-1, and late or gamma-2 genes, mainly encode for structural components needed for virion assembly, among other functions (Chen et al., 1992).

Virus egress

After the viral genes are transcribed and then translated into their products, and that the viral genome is replicated in the nucleus, viral capsids are assembled in this compartment and subsequently translocated to the cytoplasm for their exocytosis through vesicles (Ibáñez et al., 2018). During this process, viral capsid proteins such as VP5, VP23, and VP26, that are synthesized in the cytoplasm are translocated to the nucleus for the assembly of empty enclosures that are then filled with viral DNA (Ibáñez et al., 2018; Abaitua et al., 2012; Sankhala et al., 2016). During this process, three types of capsids have been described within infected cells: A- and B-type, which are devoid of viral genomes, and C-type, which contains viral DNA (McNab et al., 1998). Hence, only C-type capsids will contribute to the generation of infectious virions (Taus et al., 1998; Fig. 3).

Following capsid assembly, the maturation of this viral structure is initiated in the nucleus, where numerous tegument proteins are added to the capsid. Some of these tegument proteins are required for the capsids to leave the nucleus, such as VP1/2 and UL17 (Bucks et al., 2007; Owen et al., 2015). During their translocation to the cytoplasm, HSV capsids acquire a primary envelope at the inner nuclear membrane (INM), resulting in the primary envelopment of virions in the perinuclear space (Mettenleiter et al., 2013). In this nuclear compartment, C-type capsids are selected for progressing towards the cytoplasm (Taus et al., 1998). Notably, two

viral proteins are needed for the egress of the capsids from the nucleus to the cytosol, UL31 and UL34, which form the nuclear egress complex (NEC) of the virions (Ott et al., 2011). After these capsids reach the perinuclear space, the primary enveloped capsids fuse with the outer nuclear membrane (ONM), undergoing a de-envelopment process, with capsids being released into the cytoplasm (Mettenleiter et al., 2013; Granzow et al., 2001; Panté and Kann, 2002). Once in the cytosol, the capsids acquire additional tegument proteins (Owen et al., 2015; Fig. 3). The capsids can then be transported separately from the glycoproteins towards the cell membrane in a “separated” manner, which seemingly often occurs in neurons, or transit to the Golgi apparatus to re-envelope in this compartment for “married” exocytosis of viral particles (Snyder et al., 2006). Indeed, the movement of capsids within the cell can be “separated” or “married” (Snyder et al., 2006). In the “married” model, enveloped particles contained in vesicles are transported through axons for virion exit, while in the “separated” model naked capsids travel from the neuron cell body through the axon in parallel with vesicles containing viral glycoproteins with which they will combine at a distal site of the neuron (Ahmad and Wilson, 2020; Wisner et al., 2011; Fig. 4). The separate strategy involves the movement of capsids through microtubules and dynein-mediated transport with capsid components interacting with kinesin-1 proteins, thus enabling anterograde capsid movements through the cytoplasm (Döhner et al., 2002; Radtke et al., 2010).

The glycoproteins that will be present at the surface of the mature virion are translated in the endoplasmic reticulum (ER) and then derived onto the trans-Golgi network (TGN) from which they will be directed to multi-vesicular bodies (Wisner and Johnson, 2004; Turcotte et al., 2005; Calistri et al., 2007). From here, the glycoproteins will be exported to the cell surface from which they will be endocytosed and returned to early endosomes (Alconada et al., 1999; Hollinshead et al., 2012). Once these glycoproteins are reinternalized into the cytoplasm through endosomes, viral capsids will then fuse to them (Albecka et al., 2016) and create enveloped virions contained within exosomal vesicles that will be exported to the cell membrane for exocytosis (Hollinshead et al., 2012; Fig. 3).

Alternatively, HSVs may spread onto neighboring cells through close cell-to-cell contacts (Carmichael et al., 2018). In this case, viral proteins are directed to the boundary of contiguous cells, favoring the occurrence of membrane fusion events with viral components in a process termed virological synapse (Johnson et al., 2001). Cell infection through this mechanism allows the virus to evade the effector functions of immune components, such as antiviral antibodies that otherwise could neutralize the virus (Hook et al., 2006; Lubinski et al., 2011).

Fig. 4 Herpes simplex virus latency and reactivation. Schematic representation of herpes simplex virus infection in neurons where viral latency and reactivation occur. Neurons innervating the skin are likely infected by virus-infected epithelial cells due to close interactions. Once infected, viral capsids migrate through microtubules to the outer membrane of the cell nucleus. The genetic material is then delivered into the nucleus through nuclear pores, circularized in this compartment and maintained as an episome. During latency, high levels of the latency-associated transcript (LAT) and viral miRNAs are expressed, which leads to transcription repression of viral genes (e.g. ICP0). When the cell is exposed to virus-activating stimuli, such as UV light, fever or menstruation, reactivation of the virus infectious cycle is triggered, producing increased levels of viral proteins, such as VP16, ICP0 and thymidine kinase (TK). At this stage, viral proteins such as UL41 enhance the transcription levels of viral genes. This reactivation process leads to the replication of the virus genome and synthesis of viral proteins. Then, newly synthesized infectious particles can be released in an anterograde manner (towards the initial site of infection) or in a retrograde fashion (towards the CNS). The transport of the virus, or virus components through the axon of neurons can occur according to a “married” model, which consists of virions being transported within vesicles, or “separated” consisting of naked capsids travelling independently of vesicles that carry viral glycoproteins, with both combined at distal regions within the neuron.

Latency

Herpes simplex viruses can establish lifelong infections (Rosato and Leib, 2015). Upon the infection of the epithelium, HSVs may access the termini of sensory neurons that innervate the sites of primary infection and from there, reach the cell body of these cells, mainly neural cells of the trigeminal ganglia during facial infections and the dorsal root ganglia during genital infections (Duarte et al., 2019; Rosato and Leib, 2015). Once these viruses reach the neurons, they can establish latency in these cells, which is characterized by the circularization of the viral genome as an episome in the nucleus and the transcription of a unique RNA transcript, namely the latency-associated transcript (LAT; Margolis et al., 2007; Widener and Whitley, 2014). This transcript controls the expression of lytic genes and is likely involved in providing the virus a stealth mode in neurons which favors immune evasion. However, molecular reactivation of latent HSV has been reported, which is characterized by the expression of a subset of viral genes that yield detectable amounts of viral proteins without the yield of infectious viral particles (Feldman et al., 2002; Duarte et al., 2019; Fig. 4).

Reactivation

Several factors determine the reactivation of latent HSV infections, possibly the virus itself, host factors, and the surrounding environment (Roizman and Whitley, 2013). Some reactivation triggers include fever, exposure to UV radiation, stress and menstruation, among others (Roizman and Whitley, 2013; Fig. 4).

The LAT transcript and viral miRNAs are crucial for the establishment and maintenance of latency (Rosato and Leib, 2015; Roizman and Whitley, 2013). LAT, which is the only or main transcript undergoing transcription during latency encodes several miRNAs that increase exponentially in amount during this stage (Rosato and Leib, 2015; Roizman and Whitley, 2013). The expression of these miRNAs limit the expression of key viral genes such as *ICP0* and this reduction inhibits partially or completely viral reactivation (Roizman and Whitley, 2013; Fig. 4).

Interestingly, it has been suggested that viral reactivation requires either the activation of VP16 and the subsequent de-repression and activation of viral alpha genes, or the de-repression of alpha genes by cellular factors without the need of VP16 (Roizman and Whitley, 2013). A study performed in ganglionic organ cultures showed that the genes encoding for *ICP0* (an alpha gene), thymidine kinase (a beta gene), and VP16 and UL41 (gamma genes) are activated a few hours after explant, which is a known trigger of reactivation (Roizman and Whitley, 2013). Consequently, the transcription of LAT and several viral miRNAs was seen to decrease (Roizman and Whitley, 2013). Hence, it is suggested that viral reactivation may occur due a massive deregulation in viral genome expression that LAT and miRNAs are unable to suppress (Roizman and Whitley, 2013). Consistent with this notion, the expression of viral genes in explanted murine trigeminal ganglia coincides with LAT and miRNA degradation (Du et al., 2012). It is also suggested that viral reactivation may result from a failure of LAT and miRNAs to degrade small amounts of viral messenger RNAs encoding key viral genes (Roizman and Whitley, 2013; Fig. 4).

Once the virus reactivates within neurons in the ganglia, it may engage anterograde movements, which will lead to the spread of infectious viral particles either at peripheral tissues or within the central nervous system (Duarte et al., 2019; Fig. 4).

Evasion of host antiviral responses by HSVs

Evasion of cellular antiviral responses

Immune and non-immune cells can recognize pathogen-associated molecules thanks to numerous surface and intracellular receptors (Tognarelli et al., 2019; Suazo et al., 2015a). Pathogen-associated molecular patterns (PAMPs) consist of a set of microbial elements such as lipids, nucleic acids, carbohydrates, or proteins that may be recognized by pathogen recognition receptors (PRRs). Cell infection with pathogens can also generate damage-associated molecular patterns (DAMPs), which are danger signals released by the cells in response to viral replication and for which cellular receptors also exist (Tang et al., 2012; Johnson et al., 2013). When their corresponding receptors sense these molecules, a cascade of intracellular activating signaling pathways are initiated, which induce the activation of cellular, local and systemic antiviral responses (Mogensen, 2009).

Among the extensively studied PRRs are Toll-like receptors (TLRs), which play an important role in recognizing PAMPs and DAMPs. After binding to viral elements, TLRs elicit intracellular signaling pathways that lead to the early expression of antiviral cellular factors and the expression of soluble and membrane-bound molecules that modulate the activity of infected and non-infected neighboring cells (Alexopoulou et al., 2001; Hemmi et al., 2002; Diebold et al., 2004; Martinez-Martin and Viejo-Borbolla, 2010). Rapid detection of these molecular signals by the host will guarantee an effective antiviral response and promote the establishment of an innate and adaptive immune response (Tang et al., 2012; Johnson et al., 2013; Mogensen and Paludan, 2001).

Upon HSV infection, different TLRs, such as TLR2, TLR3, TLR7, and TLR9 are activated and can mediate antiviral responses against these viruses (Tognarelli et al., 2019). For instance, TLR2 recognizes the viral glycoprotein B and induces the activation of NF- κ B and the secretion of interleukin (IL)-8 (Cai et al., 2013). Furthermore, in response to the HSV-1 gH/gL protein complex, TLR2 in cooperation with the α v β 3 integrin leads to type-I interferon (IFN-I) production and IL-10 secretion in non-immune cells (Gianni et al., 2013, 2012). In DCs, the activation of this TLR leads to NF- κ B activation and the transcription of numerous cytokines, such as IL-6, IL-8, IL-10, IL-12, and TNF- α (Ariza et al., 2014; Fig. 5).

Fig. 5 Immune evasion by herpes simplex viruses. (A) Left panel: TLR responses and cGAS signaling in response to HSV components. TLR2 recognizes glycoprotein B which triggers NF-κB signaling. TLR3, TLR7 and TLR9 are activated by HSV infection, which triggers NF-κB and TANK-binding kinase 1 (TBK-1) signaling pathways. UL37 and VP22 inhibit the cGAS signaling pathway, but nevertheless trigger NF-κB and TBK-1 activation. On the other hand, US3, UL42, and ICP0 inhibit the activation of the NF-κB pathway. ICP27 inhibits the activation of TBK-1. Right panel: Type-I IFN response inhibition by HSV proteins. The IFN-I receptor (IFNAR) recognizes IFN-α and IFN-β and triggers IFN-I signaling pathways. Viral ubiquitin-specific protease UL36 (UL36USP) and ICP27 inhibit the activation of IFN-I responses, and the latency associated transcript LAT inhibits the production of interferon-stimulated genes (ISG). STAT-1: Signal transducer and activator of transcription 1; IRF: interferon regulatory factor; ISRE: interferon-sensitive response element, cGAS: cGMP-AMP synthase; GAS: gamma-interferon activation site. (B) Herpes simplex viruses inhibit complement activation. HSV glycoproteins C (gC) bind to C3b and C5b complement components and inhibits their interaction with other complement elements, which otherwise would lead to the formation of the membrane attack complex (MAC). (C) NK cell function is modulated by HSV. The viral glycoprotein D (gD) sequesters nectin-1, which triggers the suppression of DNAM-1. HSV also block the expression of MICA, ULBP-1, ULBP-2 and ULBP-3 in infected cells, which are NK-activating ligands. (D) HSVs hampers dendritic cell function. (1) HSVs induces apoptosis in DCs. (2) The HSV γ34.5 protein inhibits the maturation of DCs and autophagosome function. (3) the HSV ICP47 protein interferes with the translocation of peptides to the endoplasmic reticulum, mediated by the transporters associated with antigen processing (TAP), which is required for antigen presentation in MHC-I. (4) The HSV γ34.5 and ICP27 proteins inhibit the expression of CD80 and CD86 costimulatory on the DC surface, which are needed for effective T cell activation. (5) HSV infection increases cytohesin-interacting protein (CYTIP) degradation, which induces a reduction in the motility of DCs, and consequently a decrease in the migration of DCs to draining lymph nodes for antigen presentation. (6) HSVs inhibit T cell receptor (TCR) signaling pathways. gD binding to HVEM triggers inhibition of Ca²⁺ fluxes in T cells engaged for activation. The HSV US3 protein also blocks TCR signaling. (E) The HSV glycoprotein gE negatively modulates the binding of the Fc portion of antibodies to Fcγ receptors (FcγRs), thus impairing Fc-mediated functions carried out by antibodies (e.g. complement activation, opsonization and ADCC, among others).

Additionally, TLR3 has been shown to play an important role in HSV disease and is known to sense pathogen and host-derived double-stranded RNA hybrids (Alexopoulou et al., 2001). TLR3 expression in astrocytes enhances the control of HSV infection after viral access to the central nervous system (CNS) and induces type-I interferon responses while favoring the NF- κ B-dependent secretion of IL-6 and TNF- α (Reinert et al., 2012; Liu et al., 2013). Interestingly, individuals who have mutations that negatively modulate the immune response mediated by this TLR are more susceptible to developing HSV encephalitis (Zhang et al., 2007; Guo et al., 2011). Furthermore, *ex-vivo* experiments with differentiated neurons, astrocytes, and oligodendrocytes of individuals with deficiencies associated with TLR3 showed that they were more prone to viral infection and had compromised IFN- β and IFN- γ secretion (Lafaille et al., 2012; Fig. 5).

TLR7 recognizes exogenous nucleic acid molecules and has been reported to induce a response that burdens HSV infection and disease when activated with a specific agonist such as imiquimod in a genital mouse infection model (Miller et al., 1999). These findings led to the evaluation of this agonist as a therapeutic approach to treat herpetic lesions in humans, especially in immunocompromised patients suffering from acyclovir-resistant HSV-2 disease (Hirokawa et al., 2011; Kan et al., 2012; Lascaux et al., 2012). Although a clinical trial assessing the potential of imiquimod against HSV did not show promising results, somewhat similar approaches could eventually contribute to HSV control in immunocompromised patients (Schacker et al., 2002; Bernstein et al., 2005; Fig. 5).

TLR9 is mainly known to sense bacterial and viral DNA and synthetic CpG oligodeoxynucleotides (CpG ODNs), and is expressed in immune and non-immune cells (Tognarelli et al., 2019). Similar to other TLRs, TLR9 agonists can promote antiviral responses against HSV. TLR9 has been shown to sense HSV components and induce the secretion of IL-6, IL-12, and type-I IFNs, among others (Triantafilou et al., 2014; Lund et al., 2003). However, the function of TLR9 in HSV infection may not be essential for host survival upon viral challenge. Indeed, TLR9 knockout mice infected with HSV in the CNS survived an infection, although they showed more susceptibility to viral infection translating into a higher viral load in the brain (Krug et al., 2004). Interestingly, intranasal treatment of mice with CpG ODNs, which act as a TLR9 agonist, before HSV infection, increased their survival rates, reduced viral loads in the brain, and reduced the secretion of the pro-inflammatory cytokines CCL2, CCL5 and IL-6 in the CNS (Boivin et al., 2012; Fig. 5).

Besides TLRs, other host receptors are also capable of recognizing viral nucleic acids present during HSV infection that elicit strong antiviral responses and are frequently associated with stimulation of pro-inflammatory cytokines and interferon production (Diner et al., 2015). For instance, interferon- γ inducible protein 16 (IFI16) has been shown to promote the activation of the transcription factor interferon regulatory factor 3 (IRF3) and NF- κ B, which in turn induce IFN α/β and IL-6 upon HSV recognition (Dawson and Trapani, 1995; Conrady et al., 2012; Triantafilou et al., 2014). Furthermore, this receptor can silence viral gene expression by adding nucleosomes and heterochromatin marks to the viral DNA (Orzalli et al., 2013). However, the ICP0 protein of HSV-1 seems to play an important role in inhibiting IFI16 activation via targeting this protein to proteasome degradation (Johnson et al., 2013).

Additionally, cGMP-AMP synthase (cGAS), a cytosolic DNA sensor, recognizes HSV-1-related genetic material and leads to the secretion of IFN- α and IFN- β in immune and non-immune cells (Cai et al., 2014; Orzalli et al., 2015). It has also been reported that cGAS and IFI16 may act cooperatively, with cGAS promoting IFI16 stabilization (Orzalli et al., 2015). However, it has also been reported that HSV infection may deregulate the functions of these receptors. For instance, the HSV-1 tegument protein UL37 can promote the deamination of an asparagine residue in cGAS, leading to its inactivation. Furthermore, the activation of protein kinase B (PKB, AKT) upon HSV-1 infection suppresses the activity of cGAS via phosphorylation (Zhang et al., 2018; Seo et al., 2015; Fig. 5).

The DNA-dependent activator of interferon (DAI) is another nucleic acid sensor reported to induce IL-6 and IFN- β release in response to HSV-2 infection (Triantafilou et al., 2014). DAI interacts with the HSV-1 ICP0 protein and inhibits viral replication (Pham et al., 2013). Other nucleic acid sensors are retinoic acid-inducible gene 1 (RIG-I) and melanoma differentiation-associated protein 5 (MDA5), which are intracellular and recognize double-stranded RNA (Weber et al., 2006). These sensors have signaling pathways that are modulated by the VHS protein of HSVs early after infection, and results in hampering of signaling events that would otherwise promote IRF3 activation and an IFN- β -mediated antiviral response (Cotter et al., 2010; Yao and Rosenthal, 2011).

The inflammasome, a cellular multiprotein complex, can also sense viral components and initiate an antiviral response (Johnson et al., 2013). This complex promotes the secretion of inflammatory molecules such as IL-1 β (Lopez-Castejon and Brough, 2011). NLRP3, AIM2, and IFI16 are inflammasome cytoplasmatic sensors that can sense HSV components (Johnson et al., 2013). NLRP3 and IFI16 are activated early after HSV infection, which induces IL-1 β release. However, as mentioned before, ICP0 was found to inhibit IFI16 by targeting it to the proteasome (Johnson et al., 2013). On the other hand, AIM2-dependent inflammasome signaling is inhibited by the HSV-1 VP22 protein by preventing its oligomerization (Maruzuru et al., 2018).

To impair the cell capability to sense viral components, HSVs have evolved several mechanisms to modulate the activity of NF- κ B (p65), which participates in the expression of numerous immunomodulatory mediators as a transcription factor (Suazo et al., 2015a). The translocation of NF- κ B to the nucleus can be inhibited by HSVs through the hyperphosphorylation of this factor, thanks to the HSV kinase US3 (Wang et al., 2014). Also, inhibition of NF- κ B translocation to the nucleus can be mediated by the viral protein UL42, which encodes for a DNA polymerase processivity factor, which interacts with p65/RelA and p50/NF- κ B1 (NF- κ B1 forms; Zhang et al., 2013). ICP0 can also interact with p65/RelA and p50/NF- κ B1, leading to the inhibition of NF- κ B activation mediated by TNF- α (Zhang et al., 2013). Another viral protein that inhibits NF- κ B activation is the viral protein VP16, which decreases IL-8 and IFN- β production by HEK 293T HSV-infected cells (Xing et al., 2013; Wang et al., 2014). Despite the negative modulation of NF- κ B by HSV, cells infected with these viruses secrete numerous soluble mediators, such as CCL2, IL-8, IL-6, and TNF- α as seen for primary endometrial genital epithelial cells. HSV has also been reported to induce CXCL9 in the cervical

mucus of infected women (Huang et al., 2012; Fig. 5). Despite several studies showing HSV inhibition of NF- κ B, there is also evidence that activation of NF- κ B seems to be necessary for the infection process (Alvarez et al., 2020; Goodkin et al., 2003; Amici et al., 2006; Liu et al., 2008; Patel et al., 1998). Thus, the dual modulation of NF- κ B inhibition and activation by HSV-1 may be time-dependent during the infection process.

Host cells may restrict viral replication thanks to interferon responses. These cytokines induce antiviral responses in cells that secrete these molecules, as well as neighboring cells (Theofilopoulos et al., 2005). At present, there are different mechanisms by which HSVs negatively modulate the interferon responses. One of these mechanisms involves the viral protein ICP0, which binds to host IRF3, thereby inhibiting its activation and the transcription of IRF3-target genes such as type-I IFNs (Peng et al., 2009; Lin et al., 2004). The tegument protein VP16 also inhibits IRF3, and NF- κ B activation, ultimately leading to a block in IFN- β expression (Xing et al., 2013). IFN- β expression can also be inhibited by the viral ubiquitin-specific protease UL36 (UL36USP), impairing stimuli-mediated IRF3 dimerization through the de-ubiquitination of the TNF receptor-associated factor-3 (TRAF3; Wang et al., 2013; Fig. 5).

Also, HSVs may interfere with signaling events related to interferon receptors. For example, the HSV-1 ICP27 protein interferes with Signal transducer and activator of transcription 1 (STAT-1) activation needed for interferon-stimulated genes (ISG) transcription (Johnson et al., 2008). This protein has also been reported to aid in the secretion of an unknown soluble factor that has antagonizing activity over IFN-I signaling pathways of neighboring uninfected cells (Johnson and Knipe, 2010; Fig. 5).

Evasion of the innate immune response

HSVs are capable of modulating the host's innate immune response, both acellular and cellular components. The complement is an acellular set of host proteins of the innate immune response that can debilitate pathogens by mounting a membrane attack complex (MAC) over the microorganism or infected cells thanks to a cascade of controlled molecular chain reactions (Serna et al., 2016). The glycoprotein C (gC) of HSVs binds to the complement component C3b and blocks the pathways that lead to the formation of the MAC (Friedman et al., 1984; McNearney et al., 1987). This glycoprotein can also bind to the complement component C3 and inhibit complement-mediated virus inactivation or the lysis of virus-infected cells and the binding of gC to the complement component C5, blocking its down-stream activities (Lubinski et al., 2002; Hook et al., 2006; Fig. 5).

On the other hand, HSVs modulate the function of NK and NKT cells by suppressing DNAX accessory molecule-1 (DNAM-1)-dependent NK cell-mediated lysis of virus-infected cells (Grauwet et al., 2014). Importantly, glycoprotein D has been described to sequester nectin-1 from the cell surface, which was shown to impact the expression DNAM-1 on the surface of infected cells (Fig. 5) (Grauwet et al., 2014). It has also been reported that HSV infection blocks the expression of the MHC class I polypeptide-related sequence A (MICA), ULBP1, ULBP2, and ULBP3, which are NK-activating ligands (Schepis et al., 2009; Tomazin et al., 1996; Fig. 5). Additionally, HSVs downregulate the expression of the antigen-presenting molecule CD1d from the surface of HSV-infected cells, which is needed for antigen recognition by NKT cells (Godfrey et al., 2010; Yuan et al., 2006).

Dendritic cells (DCs) are immune cells that play key roles in the intercommunication between innate and adaptive immune cells (Retamal-Díaz et al., 2016). Importantly, their maturation, antiviral activity, viability and migration are affected by HSV infection (Tognarelli et al., 2019; Retamal-Díaz et al., 2016). HSVs have been reported to downregulate autophagosome activity within DCs, affecting antigen processing and presentation (Leib and Gobeil, 2012; Yordy et al., 2012). Furthermore, the ICP47 viral protein may adopt a helical hairpin structure, impairing the activity of transporters associated with antigen processing (TAP) and hence, peptide translocation to the RE (Oldham et al., 2016). HSVs also inhibit the capacity of DCs to activate T cells; the viral proteins ICP22 and γ 34.5 have been shown to downregulate the expression of important T cell co-stimulatory molecules such as CD80 and CD86 from the DC surface (Matundan and Ghiasi, 2018; Jin et al., 2009). Additionally, HSVs can affect the migration of mature DCs from the site of infection to the draining lymph nodes by increasing the degradation of cytohesin-interacting protein (CYTIP) which regulates the motility of these cells (Theodoridis et al., 2011; Tognarelli et al., 2019; Fig. 5). There is also evidence that supports a role for DCs in neuron infection. Indeed some studies have shown that the depletion of DCs (e.g. CD11c⁺/CD8 α ⁺) caused a reduction in HSV latency in neurons after ocular infection (Mott et al., 2009, 2008, 2014; Kassim et al., 2006; Mott and Ghiasi, 2008). Finally, macrophages are also affected by HSV infection with higher levels of pro-inflammatory cytokines secreted by M1 macrophages, as compared to M2 macrophages after HSV-1 infection (Martinez and Gordon, 2014). Additionally, cGAS down-stream events have also been reported to be disrupted by HSV infection, namely through viral inhibition of TANK-binding kinase 1 (TBK1) by ICP27, which interfered with IRF3-dependent type-I IFN secretion by virus-infected cells (Christensen et al., 2016).

Evasion of the adaptative immune response

HSVs encode numerous molecular factors for evading the function of antiviral antibodies and the function of T cells. The viral glycoprotein E (gE) binds to the Fc portion of antibodies thus competing with the capacity of antibodies to bind to the complement component C1q, therefore impairing one of their important functions (Lubinski et al., 2011; Para et al., 1982). Furthermore, by binding to the Fc portion of antibodies, gE inhibits the capacity of IgG antibodies bound to viral antigens to bind Fc γ receptors (Fc γ Rs), and thereby impair the phagocytosis of opsonized virus particles or capture of virus-infected cells by phagocytic immune cells (Para et al., 1982; Armour et al., 2002; Dilillo et al., 2014; Fig. 5). Additionally, HSVs negatively modulate the activation and proliferation of T cells. The binding of gD to the HVEM receptor on the surface of T cells affects intracellular calcium fluxes within these cells which are required for T cell receptor (TCR) activating signaling events after CD3 engagement (La et al., 2002).

Additionally, other HSV determinants have also been suggested to inhibit TCR-related calcium flux in T-cells (Sloan et al., 2006). Also, the HSV protein US3 can affect T cell activation by interfering with TCR signaling through the modulation of the linker for activation of T cells (LAT). The viral protein US3 reduces the ubiquitination of LAT and TNF receptor-associated factor 6 (TRAF6), leading to an overall reduced T cell activation (Yang et al., 2015). Finally, CD8⁺ T cell activation is also hampered by the capacity of HSVs to interfere with the expression of their ligands (MHC-I) on the surface of infected cells (discussed above; Hill et al., 1995; Fig. 5).

Concluding remarks

Herpes simplex viruses are highly prevalent in the human population thanks to their capacity to elicit lifelong infections and establish latency in neurons. These viruses produce a broad spectrum of diseases that range from mild to severe, and most of the individuals infected are asymptomatic. Importantly, HSVs have evolved several strategies to hijack the cellular antiviral response and the immune system. Indeed, HSVs can interfere with different steps of the host antiviral response, modulate cell viability differentially depending on the cell type, hamper the host's capacity to sense viral components, and the function of innate and adaptive immune system elements. At present, multiple drugs for treating HSVs associated diseases exist, however, these drugs are poorly effective for treating some clinical manifestations, such as skin disease and drug-resistance variants may appear. Therefore, new anti-HSVs therapies are needed to treat this type of infection and hopefully a vaccine can be developed to prevent infection.

Introduction

Epstein-Barr virus (EBV) is a ubiquitous human herpesvirus that infects at least 90% of the world's adult population (de-Thé et al., 1975). EBV was the first recognized human cancer virus: it was established as the cause of endemic Burkitt lymphoma in 1964 (Epstein et al., 1964). The worldwide burden of diseases due to EBV is enormous. In addition to endemic Burkitt lymphoma, EBV is responsible for infectious mononucleosis. EBV is a risk factor for Hodgkin lymphoma, nasopharyngeal carcinoma, and complications including cancers after solid organ or hematopoietic cell transplantation (Balfour et al., 2020). EBV is also a risk factor for autoimmune diseases, especially multiple sclerosis (Ascherio and Munger, 2010). This article discusses basic virology, epidemiology, clinical manifestations, immune responses, diagnosis, prevention, and treatment of EBV diseases, and suggests priorities for future research.

Epstein-Barr virus

EBV, also known as human herpesvirus 4 (HHV4) is a member of the *Herpesviridae* family and classified within the subfamily of gammaherpesviruses. Like other herpesviruses, the EBV genome is composed of linear, double-stranded DNA approximately 172 kbp in length packaged within an icosahedral nucleocapsid which is surrounded by a protein tegument layer, and an outer envelope with external glycoproteins (Fig. 1). The EBV tegument is composed of several large tegument proteins and tegument binding-protein proteins that are responsible for evasion from host immune surveillance, envelopment, viral morphogenesis, and reprogramming the cell for viral replication (Johannsen et al., 2004). The major envelope glycoproteins, responsible for host cell tropism and viral entry, include gp350, gp220, gH, gB, gp42, gM, gp78, gN, gp150, and gL (Sathiyamoorthy et al., 2016).

Fig. 1 Schematic diagram of Epstein-Barr virus. The major structural components of the virion are depicted. These include the envelope, which is studded with glycoproteins for binding and fusion of the virus envelope with the host cell, the tegument protein layer, the nucleocapsid, and the viral genome of double-stranded (ds) DNA.

Tropism

The major sites for EBV infection are human B lymphocytes and epithelial cells. EBV has the unique capacity to infect B cells by binding to CD21, also known as complement receptor 2 (CR2), by the EBV glycoproteins gp350 and gp220 (gp350/220) (Nemerow et al., 1989). Binding of gp350/220 triggers capping of CR2 and endocytosis of the virus. Binding of EBV to an epithelial cell is accomplished somewhat differently as CR2 is expressed at low levels on epithelial cells. EBV entry into epithelial cells occurs at the cell surface in the absence of endocytosis. Glycoproteins H and L (gHgL) are essential for viral attachment in coordination with gB to mediate fusion of the virus-cell membrane in epithelial cells (Borza et al., 2004; McShane and Longnecker, 2004; Xiao et al., 2008). Additionally, interactions between BMRF-2 β 1 family of integrins have been shown to be important for infection of polarized oropharyngeal epithelial cells with EBV (Tugizov et al., 2003).

Epidemiology

Incidence and prevalence of EBV infection

EBV is among the most common human viruses and the vast majority of the world's population has been infected by the time they reach adulthood (de-Thé et al., 1975). Seropositivity increases with age, and seropositivity appears to occur at younger ages in resource-limited countries (Piriou et al., 2012; Slyker et al., 2013; reviewed in Winter et al., 2020). The prevalence of EBV infection in children, however, varies from 10% to 90% depending on the child's age, race/ethnicity, and geographic location. Among children surveyed for EBV antibodies in the Minneapolis-St. Paul area, white non-Hispanic children did not reach 50% prevalence until age 18 whereas non-white children reached 50% prevalence by age 10 years (Condon et al., 2014). Data from the National Health and Nutrition Examination Surveys (NHANES) of US children aged 6–19 years old show the overall age-adjusted EBV antibody prevalence declined from 72% in 2003–04 to 65% in 2009–10 ($P = .027$) (Balfour et al., 2013a).

Seroprevalence of EBV has also been found to vary according to socioeconomic factors, as lower household income and education level were significantly associated with a higher prevalence of EBV antibody, that may be associated with crowdedness and lower sanitation (Balfour et al., 2013a; Smatti et al., 2018).

Incidence of primary EBV infection and infectious mononucleosis

Infectious mononucleosis most commonly affects those who have primary EBV infection during adolescence or adulthood. The overall incidence of infectious mononucleosis in the U.S. is about 500 cases per 100,000 persons per year, with the highest incidence among persons aged 15–24 years (reviewed in Luzuriaga and Sullivan, 2010). Interestingly, our prospective studies of students attending the University of Minnesota have shown the incidence of primary EBV infection during the four undergraduate years was 14.4 cases per 100 person-years. Among those with primary infection, nearly 78% (62/80) developed infectious mononucleosis (Balfour et al., 2013b; Grimm et al., 2016). Our findings are consistent to those reported by Crawford et al., who found a rate of 15.2 cases per 100 person-years of primary EBV infection among undergraduates at Edinburgh University, Scotland. However, only 24.5% (27/110) developed infectious mononucleosis (Crawford et al., 2006).

Routes of transmission

The mode of EBV acquisition varies by age and clinical characteristics. While EBV is usually spread by saliva, EBV may also be transmitted through blood, male and female genital secretions, and breastmilk. The routes of transmission are described in greater depth below and depicted graphically in Fig. 2.

Deep kissing

Among adolescents and young adults, EBV infection is acquired primarily by deep kissing, as shown by clinical observations and prospective studies of university undergraduate students, by which primary infection occurred through kissing in the absence of sexual intercourse (Balfour et al., 2013b; Grimm et al., 2016; Hoagland, 1952). EBV DNA in saliva and oral wash fluid has been detected at extremely high quantities relative to blood (median 4.8 $\log_{10}$ copies/mL) (Balfour et al., 2013b; Grimm et al., 2016). Additionally, detection of EBV DNA in the oral cavity has been shown to persist for a median of 5.2 months (Balfour et al., 2013b; Grimm et al., 2016).

Sexual intercourse

While saliva is the main route of transmission, EBV has been detected in male and female genital secretions in both infectious mononucleosis patients and healthy individuals, suggesting direct sexual spread may also contribute to transmission (Israele et al., 1991; Naher et al., 1992; Thomas et al., 2006). However, university students who engaged in deep kissing with or without penetrative sexual intercourse had the same risk of primary EBV infection compared to students who reported no kissing or sexual activity (Balfour et al., 2013b; Grimm et al., 2016).

Fig. 2 Modes of EBV transmission. The major modes of transmission are depicted, the most common being through saliva and deep kissing.

Blood

During primary EBV infection, nearly 50% of individuals will have EBV viremia (median 2.60 log₁₀ copies/mL). Therefore, EBV may be transmissible by blood, although the rate is unknown. Transmission of EBV by direct blood transfusion has been reported and resulted in infectious mononucleosis (Trottier et al., 2012).

Solid organ transplantation

EBV infections, especially when transmitted from a seropositive donor to a seronegative recipient, remain a major cause of morbidity and mortality for transplant recipients. Diseases caused by EBV infection range from acute infectious mononucleosis to those as serious as post-transplant lymphoproliferative disorder (PTLD). Transmission has been documented in solid organ transplantation and hematopoietic cell transplantation by comparing sequence variation of EBV strains (Shapiro et al., 1988; Verghese et al., 2015).

Intrafamilial spread

As described previously, EBV infection occurs at younger ages among persons from lower versus higher socioeconomic backgrounds which has been attributed to crowded living conditions (Sumaya et al., 1975). This hypothesis suggests that young children are infected by their parents, siblings, or other caregivers who are healthy carriers of the virus and periodically shed EBV in their oral secretions. Transmission among family groups was demonstrated by Henle and Henle in the Cleveland Family Study, which found evidence of spread in approximately 33% of family groups after a child in the household tested positive for EBV antibodies (Henle and Henle, 1970). Another study examining oral shedding of EBV DNA demonstrated that 28% of parents (221/800) had EBV DNA in oral wash samples, and oral EBV DNA was more prevalent in parents who identified as non-white as compared with white parents, supporting the hypothesis that parents could be a source of virus for their young children (Cederberg et al., 2019).

Breastfeeding

EBV has been detected in breast milk and may be a source of transmission to infants. The prevalence of EBV DNA was reported to be highest at 6 weeks and decreased through 18 weeks postpartum (Daud et al. 2015). Of those with EBV DNA recovered, 60% were shown to be DNAase resistant, suggesting that the viral DNA in the breast milk was encapsidated and therefore infectious (Daud et al. 2015). Indeed, EBV infection in infants <6 months of age has been reported (Piriou et al., 2012). However, a study of Japanese infants indicated that the seroprevalence of babies who were breastfed or exclusively bottle-fed did not differ, suggesting that breast milk was not a source of EBV transmission (Kusuhara et al., 1997).

EBV diseases

Infectious mononucleosis

Establishing EBV as the cause of infectious mononucleosis

The clinical syndrome we now know as infectious mononucleosis was first described in the 1880s by Nil Filatov, a Russian pediatrician, and Emil Pfeiffer, a German pediatrician (reviewed in Balfour et al., 2020). The term “infectious mononucleosis” was

coined in 1920 by Sprunt and Evans, who recognized that this was an acute infectious disease accompanied by the laboratory finding of large numbers of circulating mononuclear cells (Sprunt and Evans, 1920). It was especially important to distinguish these atypical lymphocytes from leukemic cells (Downey and McKinlay, 1923; Sprunt and Evans, 1920), because the etiologic agent had not yet been discovered, so there was no specific diagnostic test for infectious mononucleosis. EBV was established as the major cause of infectious mononucleosis in 1967 when a technologist in the Henle laboratory who had donated blood as a control for experiments involving EBV, came down with the disease and developed antibodies against the virus (reviewed in Balfour et al., 2020; Henle et al., 1968).

Incubation period

The incubation period of infectious mononucleosis, based on careful history taking (Hoagland, 1952, 1964; Svedmyr et al., 1984) and our own prospective studies (Balfour et al., 2015), is 32–49 days. The viral and immunologic events during the incubation period will be described in the “Immune responses” section below.

Clinical features of the acute illness

Eighty undergraduate university students (ages 18–22 years) acquired a primary EBV infection during 2 prospective surveillance studies at the University of Minnesota (Balfour et al., 2013b; Grimm et al., 2016). These studies enabled us to characterize the entire clinical course of infectious mononucleosis in adolescents and young adults. Of the 80 primary EBV infections, 62 (77.5%) manifested as infectious mononucleosis (defined by having at least 2 of the following: sore throat, cervical lymphadenopathy, fever, fatigue), 8 (10%) were symptomatic but did not meet the criteria for infectious mononucleosis, and 10 (12.5%) were entirely asymptomatic. The clinical findings of the 70 participants who were symptomatic are summarized in Table 1. Pharyngitis can be quite severe, as illustrated in Fig. 3, which shows a patient’s sore throat on the tenth day of illness with an enlarged uvula kissing the left tonsil. The median duration of illness was 18 days (mean, 19 days). The only consistent laboratory abnormalities were atypical lymphocytosis and transiently elevated alanine aminotransferase, which was indicative of some degree of hepatocellular damage. Indeed, hepatic involvement is not a complication, but a regularly occurring finding in acute infectious mononucleosis (Hoagland and McCluskey, 1955).

The time course of EBV DNA in oral secretions and blood, and the EBV-specific antibody responses to the viral infection are shown in Fig. 4. EBV DNA is present in oral secretions several days before the host mounts an EBV viral capsid antigen (VCA) IgM antibody response. EBV VCA IgG antibodies become detectable on about the 10th day of illness and persist for life. In contrast, EBV VCA IgM antibodies disappear about 3 months after the onset of illness in most patients, but may linger for up to a year in some individuals. EBV nuclear antigen (EBNA) IgG antibodies are the slowest to appear, but once present persist for life in the majority of cases.

Complications of the acute illness

Complications may be due to tissue-invasive viral infection or immunologic dysfunction. Two of our female participants had complications. One developed acute pancreatitis and the other severe pancytopenia. Both participants recovered completely without sequelae. Table 2 lists the complications whose frequency is estimated to be at least 1%. Complications described in fewer than 1% of patients are: conjunctivitis, hemophagocytic syndrome, myocarditis, neurologic diseases other than meningoencephalitis, pancreatitis, parotitis, pericarditis, pneumonitis, and psychological disorders (Connelly and DeWitt, 1994; Jensen, 2000). Splenic rupture is a rare but feared complication (Hoagland and Henson, 1957), which may be avoided by keeping patients out of contact sports for 3 weeks after the onset of illness or until radiologic imaging shows the spleen to be of relatively normal size.

Table 1 Clinical findings of primary EBV infection in 70 prospectively followed symptomatic students.

Feature	No. positive	Proportion positive	Median duration (days) ^a
Sore throat	66	94%	7.5
Swollen or tender cervical lymphadenopathy	56	80%	15.0
Fatigue	50	71%	15.5
Upper respiratory symptoms(cough, runny nose, nasal stuffiness)	44	63%	8.0
Decreased appetite	37	53%	10.0
Headache	37	53%	8.0
Fever	33	47%	5.5
Body aches	32	46%	8.0
Abdominal pain	9	13%	16.0

^aMedian days for participants with the symptom.

Fig. 3 Marked pharyngitis on the 10th day of symptoms of infectious mononucleosis. The uvula is swollen and nearly touches the swollen right tonsil.

Fig. 4 EBV DNA is present in oral secretions several days before the host mounts an EBV viral capsid antigen (VCA) IgM antibody response. EBV VCA IgG antibodies become detectable on about the 10th day of illness and persist for life. In contrast, EBV VCA IgM antibodies disappear about 3 months after the onset of illness in most patients, but may linger for up to a year in some individuals. EBV nuclear antigen (EBNA) IgG antibodies are the slowest to appear, but once present persist for life in the majority of cases.

Table 2 Complications experienced by at least 1% of patients with infectious mononucleosis.

Complication	Comment
Upper airway obstruction	Due to oropharyngeal swelling especially if tonsils are present. May require anti-inflammatory medication
Meningoencephalitis	Can be fatal
Anemia, thrombocytopenia, and/or leukopenia	Transient; thought to be autoimmune
Maculopapular rash	Usually associated with administration of penicillin or its derivatives

Chronic infectious mononucleosis

A minority of persons who have infectious mononucleosis never recover completely. We have observed two patterns of this, which we call chronic infectious mononucleosis. The most common pattern is recovery from the initial disease, but recurrence of symptoms months to years later. The other pattern is continuation of symptoms that last indefinitely. Symptoms, in order of frequency, are: fatigue, weakness, joint pain, increased susceptibility to infections, diminished cognition, thyroid disorders, hypersomnia, and tender cervical lymphadenopathy. EBV DNA absent in the blood. Patients tend to have very high plasma or serum IgG antibody levels against EBV VCA; modestly elevated plasma or serum antibody levels against EBNA IgG, and the absence of circulating VCA IgM antibodies.

Chronic active EBV

A few patients who become infected with EBV never clear the viral infection (Kimura and Cohen, 2017). This entity is called chronic active EBV disease. Some develop fulminant infectious mononucleosis and die within days or weeks. Others develop a more chronic course with infectious mononucleosis-like symptoms such as fever, persistent lymphadenopathy, splenomegaly, and hepatitis. These patients are unable to control EBV infection and have infiltration of tissues by EBV positive T cells, natural killer (NK) cells, or B cells. The disease is characterized by continuous high levels of EBV in the blood. The only effective treatment is a hematopoietic cell transplant.

EBV and lymphomatous malignancies

EBV has been associated with a farrago of malignant diseases beginning with endemic Burkitt lymphoma. EBV appears necessary but not sufficient by itself to induce these conditions. Genetic, geographic, and environmental factors likely conspire with EBV to produce such malignant outcomes.

Endemic Burkitt lymphoma

EBV was discovered in 1964 by examining Burkitt lymphoma cells under an electron microscope (Epstein et al., 1964). Thus, EBV became the first recognized human cancer virus. Endemic Burkitt lymphoma is still a major cause of childhood cancer in East Africa. A study from Malawi reported that between 2011 and 2013, 74 (65%) of 114 lymphomas in children 2–16 years of age were Burkitt lymphoma (El-Mallawany et al., 2017). Endemic Burkitt lymphoma is a good target for preventive vaccine trials because of its gravity, its relatively short incubation period (as compared with nasopharyngeal carcinoma for example), and the existence of distinct geographic foci with a high incidence of Burkitt lymphoma (Rainey et al., 2007).

Hodgkin lymphoma

The link between infectious mononucleosis and Hodgkin lymphoma was suspected, based on clinical, hematological, and serological characteristics, years before EBV was discovered to be a key player in both (Kenis et al., 1958; Massey et al., 1953). EBV has been associated with ~40% of Hodgkin lymphomas as documented by finding EBV RNA or EBV protein in lymphoma cells using in situ hybridization or immunohistochemistry (Glaser et al., 1997). Infectious mononucleosis has clearly been established as a risk factor for Hodgkin lymphoma with a median time of 2.9 years from onset of infectious mononucleosis to lymphoma (Hjalgrim et al., 2003).

Other B-cell malignancies

Besides endemic Burkitt lymphoma and Hodgkin lymphoma, EBV is implicated in a number of other B-cell malignancies, which include diffuse large B-cell lymphoma, plasmablastic lymphoma, primary effusion lymphoma, and lymphomatoid granulomatosis (reviewed in Ok et al., 2015).

T cell and NK cell malignancies

EBV driven T-cell and NK cell lymphomas are not as common as EBV-spurred B-cell lymphomas. The entities associated with EBV are: extranodal NK/T-cell lymphoma, nasal type, aggressive NK-cell leukemia, peripheral T-cell lymphoma, not otherwise specified, and primary EBV-positive nodal T or NK cell lymphoma (reviewed in Montes-Mojarro et al., 2020).

EBV and epithelioid malignancies

Nasopharyngeal carcinoma

Nasopharyngeal carcinoma has a unique geographical distribution and is a common cancer in China, especially Southern China, the Arctic, Southeast Asia, and Northern Africa (Petersson, 2015). Risk factors include race, family, male sex, and possibly diet (Petersson, 2015). The association of nasopharyngeal carcinoma with EBV was first appreciated by Old et al. who tested 352 patients and found that 64/94 (68%) of those with either nasopharyngeal carcinoma or Burkitt lymphoma had circulating antibodies against an antigen derived from Burkitt lymphoma cells as compared with 30/258 (12%) of persons who were healthy or had other diseases ($P < .0001$, Fisher's exact test, two sided) (Old et al., 1966). Harald zur Hausen et al. clinched the connection between EBV and nasopharyngeal carcinoma by demonstrating EBV DNA in biopsies from Burkitt lymphoma and nasopharyngeal carcinoma (zur Hausen et al., 1970). Nasopharyngeal carcinoma is characterized by relatively high levels of EBV-specific circulating IgA, which increase as the disease progresses (Henle and Henle, 1976; Wara et al., 1975). EBV DNA levels in the plasma or serum can also be used to monitor the clinical course (Lo et al., 1999).

Gastric cancer

Approximately 9% of gastric adenocarcinomas are EBV-positive (Camargo et al., 2014). The histology of EBV-positive gastric carcinoma has been described as very similar to that of undifferentiated nasopharyngeal carcinoma (Shibata et al., 1991). These authors found that EBV was present in epithelial cells but not in the reactive lymphocytes that were invading the tumor. Patients with this entity had a better prognosis than those whose gastric carcinoma was EBV-negative (Camargo et al., 2014).

EBV and immunodeficiency states

EBV is able to establish and maintain persistent infection in memory B lymphocytes (Thorley-Lawson and Gross, 2004). These cells predominantly reside in the germinal centers of lymph nodes, tonsils, and spleen. However, a small number circulate in the peripheral blood (Laichalk et al., 2002) and are capable of initiating an active viral infection under certain circumstances, especially when the host is subject to intrinsic or extrinsic immunosuppression.

Posttransplant lymphoproliferative disorder

Posttransplant lymphoproliferative disorder, a complication of solid organ and hematopoietic cell transplantation, consists of a spectrum of disorders from benign polyclonal B-cell proliferation to malignant lymphoma. EBV is the main pathogenic driver in most but not all cases. We have shown that high levels of EBV DNAemia are a risk factor for developing this condition (Holman et al., 2012). The clinical features include fever, weight loss, fatigue, malaise, and lymph node enlargement anywhere in the body. Extra-nodal involvement is also common (Dharmidharka, 2018).

EBV-positive mucocutaneous ulcer

This benign form of posttransplant lymphoproliferative disorder consists of well-circumscribed mucosal ulcers with patchy necrosis located on the lip, oral cavity or gastrointestinal tract (Hart et al., 2014). Ulcer biopsy specimens are strongly positive for RBV-encoded small RNAs by in situ hybridization, but EBV DNAemia is absent. Patients recover completely when immunosuppression is reduced.

AIDS

Patients with HIV/AIDS are prone to EBV-driven complications, such as oral hairy leukoplakia, smooth muscle tumors, mucosa-associated lymphoid tissue lesions, and a variety of lymphomas with a predilection for the central nervous system (McClain, 2001). Untreated AIDS patients have progressively worse immune function, largely due to depletion of CD4+ T cells. Improved antiretroviral therapies have reduced the incidence of AIDS-related lymphomas, which suggests that an intact immune system is required to keep EBV at bay (Besson et al., 2001).

Hemophagocytic lymphohistiocytosis

This disease, also called hemophagocytosis, has both a genetic and an acquired form (Rosado and Kim, 2013). The genetic form was first described by Farquhar and Claireaux (1952) and the acquired form by Risdall et al. (1979). A number of microbial pathogens have been considered to be the trigger, but EBV is the most prevalent culprit. The disease is characterized by severe hyperinflammation, with the prominent clinical findings being fever and splenomegaly accompanied by numerous laboratory abnormalities including decreased numbers of red cells, platelets, neutrophils, and NK cells, and elevation of triglycerides and ferritin. Hemophagocytosis is present in tissues especially the bone marrow, spleen and lymph nodes. The genetic defects associated with HLH have been summarized by Marsh (2018).

Hypersensitivity to mosquito bites

Hypersensitivity to mosquito bites is a rare but often fatal disease that occurs most frequently in Japanese children (reviewed by Asada, 2007). Patients have intense skin reactions at the sites of mosquito bites and also develop fever, lymphadenopathy and hepatosplenomegaly. The pathogenesis involves EBV infection of NK cells with attendant immune dysregulation.

Primary immunodeficiencies

Numerous primary immunodeficiencies have been associated with uncontrolled EBV proliferation and more certainly will be discovered (Cohen and Meyts, 2020). The best known of these is x-linked lymphoproliferative disease, also known as Duncan's syndrome, which was discovered in the 1970s by Purtilo et al. (1975) and has recently been reviewed (Panchal et al., 2018). Two others involve dysfunction of nuclear factor kappa-light-chain-enhancer of activated B cells (Arjunaraja et al., 2018; Hoeger et al., 2017). A patient with CD70 deficiency has been described who experienced periodic fever, tonsillitis, cervical lymphadenitis, and EBV viremia (Caorsi et al., 2017). Activated PI3K δ syndrome is a combined immunodeficiency resulting in recurrent sinopulmonary infections, lymphoproliferation, and susceptibility to herpesvirus infections especially EBV (Carpier and Lucas, 2017).

Autoimmune diseases

Multiple sclerosis

EBV has been considered a risk factor for a number of autoimmune diseases but the strongest association is EBV and multiple sclerosis (MS). There is convincing evidence that EBV is the major environmental risk factor for developing MS. First, practically all MS patients have been infected by EBV (Ascherio and Munch, 2000). Second, their EBV-specific antibody titers are elevated, especially against EBNA-1 (Banwell et al., 2007; Munger et al., 2011). Third, a history of infectious mononucleosis increases the risk of developing MS (Handel et al., 2010). Fourth, EBV-specific CD8+ T cell responses are elevated in active MS (Angelini et al., 2013). Fifth, EBV antigens that reflect active viral replication are present in the brain tissue of MS patients (Moreno et al., 2018; Serafini et al., 2013). Furthermore, EBV-specific adoptive T cell therapy has shown promise in modifying the severity of MS, which supports the concept that active EBV infection is responsible, at least in part, for disease progression (Pender et al., 2014, 2018).

Other autoimmune diseases

Using a unique genetic computational algorithm, Harley and colleagues recently provided compelling evidence that EBV is a risk factor especially for systemic lupus erythematosus, but also rheumatoid arthritis, inflammatory bowel disease, type 1 diabetes, juvenile idiopathic arthritis and celiac disease (Harley et al., 2018). The basis for this observation was that EBV nuclear antigen 2 shared risk loci with human transcription factors and cofactors for those above mentioned 7 autoimmune diseases.

Immune responses

Incubation period

During primary EBV infection, viral replication is first detected in the oral cavity and then moves to the blood during the incubation period (Balfour et al., 2013b). The incubation period of EBV is 42 days, on average (Balfour et al., 2013b; Grimm et al., 2016). During this time, starting about 2 weeks prior to symptom onset, a systemic type I interferon gene signature can be observed in peripheral blood mononuclear cells, waning by the time symptoms begin due to rapid CD8 T cell expansion (Dunmire et al., 2014, 2015).

Acute phase

During acute infectious mononucleosis, CD8 T cells undergo rapid expansion and comprise both EBV-specific and non-EBV-specific cells (Hislop et al., 2007). Tetramer-positive EBV specific CD8 T cells rapidly increase at the time of symptom onset and exhibit elevated levels of CD38+ for several weeks. CD4 T cells are not significantly affected but the cells are activated and respond to EBV MHC class II tetramers (Dunmire et al., 2015; Long et al., 2013). Meanwhile, as shown in Fig. 4, IgM antibodies to EBV VCA are produced and persist for 4–6 weeks. IgG antibodies against EBV VCA begin to be produced and can be detected during the first month of symptoms (Balfour et al., 2013b; Grimm et al., 2016).

Convalescent phase

T-cell lymphocytosis resolves during convalescence (3–6 months post-infection), in which there is a reduction in the number of T-cells with activation markers and the cytotoxic T-cell response is diminished. The production of antibodies against EBV VCA has been established and anti-EBNA IgG beginning to appear approximately 91 days post-symptom onset (Balfour et al., 2013b; Grimm et al., 2016).

Latency

Latency is the state of persistent viral infection without viral production and is a hallmark of herpesviruses. During latency, EBV persists primarily in memory B-cells and sometimes in epithelial cells and may be stimulated to reactivate EBV (Odumade et al., 2011). This causes virus to be produced that can reinfect new B cells and epithelial cells, becoming a source of viral transmission (described in the “Epidemiology” section above).

Diagnosis of infectious mononucleosis

Infectious mononucleosis due to EBV should be suspected in patients, especially young adults, presenting with at least two of the following findings: sore throat, cervical lymphadenopathy, fever, and fatigue. Clinical signs of pharyngitis with swelling of the tonsils and lymphadenopathy can also be indicative of infectious mononucleosis (Balfour et al., 2013b; Grimm et al., 2016).

A heterophile antibody test utilizing commercially available test kits is a relatively inexpensive and rapid diagnostic tool that supports the clinical diagnosis. Heterophile antibodies by definition are not specific. The presence of heterophile antibodies are detected by broad reactivity with non-human mammalian red blood cells (Balfour et al., 2015). While heterophile antibody tests are most commonly used to diagnose infectious mononucleosis, their results should be interpreted with caution due to their poor sensitivity and specificity. Additionally, heterophile antibodies can be detectable for a year or more and therefore are not always diagnostic of an acute EBV infection (Marshall-Andon and Heinz, 2017). However, if a patient presents with the clinical signs and symptoms of infectious mononucleosis, additional diagnostic procedures are not usually necessary to further confirm diagnosis.

Antibody testing for diagnosis of primary EBV infection

Enzyme immunoassays (EIAs) for EBV VCA IgM and VCA IgG in combination with EBNA IgG can be utilized for confirming the diagnosis of primary EBV infections (Table 3). Individuals who are negative for all three antibodies are considered EBV naïve and susceptible to a primary EBV infection. Everyone who experiences a primary EBV infection develops EBV IgG antibodies to VCA; however, it can take several weeks for them to become detectable depending on assay platform (Balfour et al., 2013b). Therefore, clinicians should order an EBV panel consisting of all three EBV-specific antibodies. A positive VCA IgM response or a positive VCA IgG response coupled with a negative EBNA response is indicative of a current or recent EBV infection (Balfour et al., 2015).

Diagnosis of EBV infection in immunocompromised patients

Monitoring of EBV infection in immunocompromised patients is important to identify complications; specifically, posttransplant lymphoproliferative disorder (PTLD), in patients who have recently undergone a transplantation. Due to an immunocompromised status, a patient might not produce detectable antibodies while experiencing an EBV infection. In this case, the best test for diagnosis and monitoring EBV infections in immunocompromised individuals is a blood viral load or quantitative EBV DNA assay performed using a polymerase chain reaction (PCR) platform (Holman et al., 2012).

Prevention of EBV infection

Prevention of primary EBV infection

Approximately 90% of individuals worldwide are infected with EBV with the majority of primary infections occurring in children as shown in prevalence investigations (Balfour et al., 2013a). Individuals can reduce their risk of infection by utilizing hygienic measures including hand washing and avoiding salivary contamination from infected individuals through intimate or other close contact.

Table 3 Staging EBV infection by enzyme immunoassay antibody results (Balfour et al., 2015).

Stage of infection	Time after onset of illness	VCA IgM	VCA IgG	EBNA-1 IgG
EBV Naïve	–	Negative	Negative	Negative
Acute Primary Infection	0–3 Weeks	Positive	Negative or Positive	Negative
Subacute Infection	4 Weeks–3 months	Positive	Positive	Negative
Convalescent Infection	4–6 Months	Negative or Positive	Positive	Negative or Positive
Past Infection	>6 Months	Negative	Positive	Positive

EBV vaccine

Due to the plethora of diseases associated with EBV, the development of prophylactic vaccine is a priority for researchers. A prophylactic EBV vaccine could potentially prevent infectious mononucleosis, EBV-associated cancers, and multiple sclerosis (MS). A vaccine could also potentially prevent severe illness or even death from EBV infection following transplantation, especially in pediatric patients who have not been exposed to the virus and have no immunity against it. Several prophylactic EBV vaccine candidates have been given to people, but none have been sufficiently studied to establish safety and efficacy for FDA approval (Balfour et al., 2020).

EBV vaccines have been in the works for decades, with the first phase 1 clinical trial published by researchers from Beijing China in 1995 (Gu et al., 1995). The vaccine contained the EBV membrane antigen gp220-340 as the immunogen because antibodies against EBV gp350 are closely related to neutralizing antibodies, which should prevent EBV from infecting B lymphocytes (Pearson et al., 1970). After efficacy was shown in a rabbit model, safety studies were conducted by vaccinating adult and children previously infected by EBV. Following confirmation of safety, the gp220-340 vaccine was further evaluated in EBV-naïve children to test antibody responses during 16 months of follow-up. Results of the prospective study indicated that three out of the nine vaccinees and all ten in the control group became infected with wild-type EBV. These results hint at efficacy; however, no follow-up work on the vaccine has been reported likely because it contains a live vaccinia vector, which has been shown to produce a high rate of adverse events following vaccination (Belongia and Naleway, 2003).

In 1999, researchers produced a recombinant subunit EBV gp350 candidate vaccine in Chinese hamster ovary cells that evoked gp350 and neutralizing antibodies in rabbits (Jackman et al., 1999). A vaccine containing this or a similar immunogen has been subject to multiple clinical trials. EBV-naïve and EBV-experienced young adults, 18–25 years old, were recruited to participate in a phase 1 study that examined the safety and immunogenicity of a three-dose vaccine series given via intramuscular injection (Moutschen et al., 2007). A phase 2 placebo controlled, double-blind randomized control trial was conducted in participants aged 16–25 years old, who were randomized to receive the gp350 recombinant vaccine with adjuvant system 04 (AS04). This study examined the safety, immunogenicity and efficiency of the vaccine. While the results indicated that the vaccine did not prevent primary EBV infection, it did appear that the vaccine had a significant effect on reducing clinical disease (Sokal et al., 2007). Lastly, this recombinant subunit EBV gp350 vaccine was tested in 16 pediatric kidney transplant recipients, a population with a very high risk of developing PTLD. While the study population was too small to provide any statistical evaluation metrics, it did demonstrate the safety of this vaccine in children receiving kidney transplants.

Another proposed EBV vaccine strategy has been to control the expansion of EBV-infected B-cells by generating CD8+ T cell immunity to EBNA5. A phase 1 trial conducted in EBV-naïve individuals showed that none of the vaccinated cohort developed infectious mononucleosis providing evidence that the vaccine might prevent symptomatic primary EBV infection. However, this study was conducted in a very limited cohort, with only nine vaccine recipients and 4 placebo recipients (Elliott et al., 2008).

The introduction of an FDA approved prophylactic EBV vaccine has the potential to reduce the burden associated with many acute and chronic EBV diseases. The National Cancer Institute has recommended more clinical trials be conducted to test the safety and efficacy of a prophylactic EBV vaccine to prevent infectious mononucleosis and associated cancers (Cohen et al. 2011). Further research and funding must be provided to advance the development of an EBV vaccine.

Treatment of EBV infection

Infectious mononucleosis

Nonspecific management

Antipyretics

Acetaminophen is generally prescribed rather than aspirin because of concern that aspirin might increase the risk of splenic hemorrhage (Auwaerter, 2004; Eichner, 1996; Luzuriaga and Sullivan, 2010). Fever usually subsides within a week but has been reported to persist for up to 3 weeks (Hoagland, 1960).

Analgesics

Pain control is important during the acute stage of infectious mononucleosis, especially for patients whose sore throat keeps them up at night. Management strategies include acetaminophen, nonsteroidal anti-inflammatory drugs, saltwater gargles, anesthetic throat lozenges, or viscous lidocaine hydrochloride (Auwaerter, 2004; Eichner, 1996; Luzuriaga and Sullivan, 2010). Codeine sulfate is appropriate for patients who do not respond to nonnarcotic pain control.

Fluids and nutrition

Attention to fluid intake is important, especially for febrile patients. Maintaining adequate nutrition is also important but can be challenging because many patients are anorexic during the first weeks of illness likely due to subclinical hepatitis.

Limitation of activities

Bed rest is unnecessary, but contact sports are contraindicated as mentioned above. Patients generally regulate daily activities to the level of their exercise tolerance.

Corticosteroids

Prescribing corticosteroids for infectious mononucleosis is a relatively common practice. However, an evidence-based literature review of seven studies concluded that there is insufficient evidence to recommend steroids for control of the symptoms of infectious mononucleosis (Candy and Hotopf, 2006). Most clinicians reserve corticosteroids for management of complications, such as impending airway obstruction, autoimmune anemia, and autoimmune thrombocytopenia (Auwaerter, 2004; Eichner, 1996; Luzuriaga and Sullivan, 2010; Putukian et al., 2008).

Specific antiviral therapy

Nucleosides are the only class of antiviral drugs evaluated for treatment of EBV infections in controlled clinical trials. These nucleosides are DNA polymerase inhibitors. They are inactive as given, but when anabolized intracellularly to the active nucleoside triphosphate form, they act as faulty substrates for viral DNA polymerase, disrupting or terminating synthesis of the DNA chain (reviewed in Balfour, 1999). The monophosphorylation step is accomplished more efficiently by virus-encoded enzymes than by host cell nucleoside kinases, thus enhancing the activity of these compounds in herpesvirus-infected cells as compared with uninfected cells (Elion et al., 1977). The enzyme responsible for monophosphorylation in EBV-infected cells is believed to be a virus-encoded protein kinase rather than a thymidine kinase (Gustafson et al., 1998; Meng et al., 2010). To date, no drug has been approved for treatment of EBV diseases by regulatory agencies.

Acyclovir

Intravenous and oral acyclovir have been studied for treatment of infectious mononucleosis (Andersson et al., 1986, 1987; Pagano et al., 1983; van der Horst et al., 1991). One trial evaluated oral acyclovir and prednisolone versus placebo (Tynell et al., 1996). These trials have uniformly shown a reduction of EBV in the oral compartment, but clinical efficacy was not demonstrated.

Valacyclovir

Valacyclovir is an oral prodrug of acyclovir with an oral bioavailability of at least 50%, compared with 10–20% for the parent compound (Weller et al., 2009). Hence, it has the potential to be more effective than acyclovir. We evaluated valacyclovir (3 g/day for 14 days) versus no antiviral drug in 20 University of Minnesota undergraduates with infectious mononucleosis due to laboratory-confirmed primary EBV infection (Balfour et al., 2007). There was a significant reduction in viral load in the oral compartment but not in the blood. The number of reported symptoms and the severity of illness were reduced significantly among the 10 valacyclovir recipients compared with the 10 control subjects. Criticisms of our study are the small number of subjects enrolled and the lack of a placebo. However, the results of this trial warrant further investigation because valacyclovir is very safe (Tyring et al., 2002) and relatively inexpensive now that generic formulations are available.

Ganciclovir and valganciclovir

Ganciclovir is active against EBV in vitro (Ballout et al., 2007; Lin et al., 1984; Romain et al., 2010), and ganciclovir or its oral prodrug, valganciclovir, has been used to prevent posttransplant EBV disease, as discussed below. However, there are no controlled trials to support a clinical benefit of ganciclovir for treatment of EBV diseases.

Tenofovir

Tenofovir and its congeners are nucleoside reverse transcriptase inhibitors approved for prevention and treatment of HIV/AIDS, and for the treatment of chronic hepatitis B infection. An elegant laboratory study has just shown that tenofovir is a potent inhibitor of EBV lytic DNA replication, which encourages investigation of these compounds for potential clinical use (Drosu et al., 2020).

Management of severe EBV disease

Potentially serious EBV disease in transplant patients is managed initially by a reduction of immunosuppression (Paya et al., 1999). If that is insufficient to bring the viral infection under control, humanized monoclonal anti-CD20 antibody (rituximab) may be administered, sometimes in conjunction with chemotherapy (Elstrom et al., 2006). In refractory cases, adoptive immunotherapy with primed CD8+T cells (Haque et al., 2007; Khanna et al., 1999) is occasionally successful.

Future challenges

Prospects for future prophylactic EBV vaccines

An EBV vaccine has the potential to greatly reduce the burden associated with primary EBV infections and associated illnesses. A gp350 subunit vaccine, similar to the one used in the phase 2 trial is currently being developed at the University of Minnesota in collaboration with an industrial partner. Additionally, researchers have also produced a subunit vaccine with a Newcastle disease virus (NDV) virus-like particle containing EBV gp350/220 fused to an NDV-fusion protein. This vaccine product has been shown to produce gp350 and neutralizing antibodies in mouse models (Ogembo et al., 2015). Lastly, the Cohen research group has also

constructed a candidate EBV vaccine that consists of an ectodomain of gp350 fused to ferritin or encapsulin. This vaccine product has been shown to product EBV neutralizing antibodies in monkey and mouse models (Kanekiyo et al., 2015).

With several gp350 based vaccines showing promise, priorities for future research include the development of a plan to determine vaccine efficacy for preventing EBV associated malignancies. Additionally, sufficient funding is required to move the EBV vaccine candidates from their current stage of preclinical research and development to a phase I clinical trial. It is essential that collaborations between academic, industry, and government organizations continue to be established and nurtured to accelerate EBV vaccine development.

Development of EBV-specific cell-mediated immunity using an interferon-gamma assay

In recent years, the roles of T-cell based immunodiagnostic assays have expanded to the diagnosis and risk identification for several infectious diseases including cytomegalovirus (CMV). CMV, a member of the herpesvirus family, is structurally similar to EBV with a relatively large linear double-stranded DNA genome and a highly ordered icosahedral-shaped nucleocapsid (Liu and Zhou, 2007). Researchers have developed a cell-mediated immunity monitoring protocol using an interferon-gamma assay for the CMV. Several studies have shown that the risk of CMV infection after organ and hematopoietic cell transplantation may be predicted by assessing CMV-specific cell-mediated immunity during pretransplant and posttransplant periods (Chemaly et al., 2020; Jarque et al., 2020). Similar laboratory techniques should be developed for EBV to monitor EBV cell-mediated immunity (EBV-CMI) responses during vaccine clinical trials. EBV-CMI may be an important index of protection against symptomatic EBV infections and in predicting the populations at highest risk for EBV-associated diseases and their prognosis (Kim, 2020).

Funding

This work was supported by grants from the University of Minnesota International Center for Antiviral Research and Epidemiology, the Richard M. Schulze Family Foundation, the Randy Shaver Cancer Research and Community Fund, the Matt Cwiertny Memorial Foundation, and the University of Minnesota Foundation.

Glossary

Antiviral therapy A medication used to treat viral infection in individuals at risk for severe disease. Usually antiviral agents specifically interfere with aspects of the viral, and not the host, life cycle.

Capsid The innermost, proteinaceous compartment of enveloped viruses such as CMV. It typically contains viral proteins important in virion assembly. The term “nucleocapsid” refers to the viral nucleic acid/capsid protein complexes containing viral genome.

Cytomegalovirus Literally, the word “cytomegaly” means “large cell.” Hence, cytomegalovirus infection of cells characteristically induces cell enlargement, often with accompanying intracellular inclusions.

DNA vaccine Vaccine strategy in which a recombinant DNA molecular encoding a viral gene product (protein) of interest is administered to an individual, toward the goal of inducing a protective immune response.

Envelope The outermost layer of the virion particle, consisting of a prototypical phospholipid bilayer which is studded with viral proteins, in particular viral glycoproteins that serve as ligands for host cell receptors (and are targets of host immune responses that important in convalescence and protection against infection).

HAART Therapy HAART is an acronym for “highly active anti-retroviral therapy.” This is any combination of HIV therapies that promotes control of HIV, reconstitution of cellular (particularly CD4+ cell) immunity, and resolution of HIV-associated opportunistic infections.

mRNA vaccine A novel vaccine strategy, first evaluated in human subjects in the context of the COVID-19 pandemic, in which a messenger RNA (mRNA) encoding a viral gene product (protein) of interest is administered to an individual, toward the goal of inducing a protective immune response.

Subunit vaccine A vaccine designed and manufactured to induce antibody responses against one or more particular proteins or constituents of a pathogenic virus. Subunit vaccines typically utilized cloning technologies to express immunological targets of interest in a variety of expression systems.

Tegument The amorphous, proteinaceous layer of a CMV virion lying between the envelope and the nucleocapsid. It typically contains viral proteins, including many phosphorylated proteins, that are important in viral replication.

Vector vaccine A vaccine approach in which an immunogen of interest (such as SARS-CoV-2 Spike protein) is inserted into another, attenuated viral vector. Immunization of the individual with the vector in turn induces an immune response the gene product of the pathogen, resulting in protective immunity against that virus.

Virion An intact and infectious viral particle, consisting of the envelope, tegument, and nucleocapsid.

Introduction

Long before viruses were discovered, the impact of CMV on human health was recognized by a German pathologist, Ribbert, who noted characteristic cytoplasmic inclusions (sometimes referred to as “Owl’s Eyes” inclusions) in an autopsy of a still born infant with congenital CMV infection in 1881 (Riley, 1997). Three groups independently isolated CMV in cell culture in the mid-1950s, and in 1960 Thomas Weller proposed the term “cytomegalovirus” to describe this agent. The identification of the agent in the urine of infants with generalized disease confirmed the importance of CMV as a congenital pathogen. Subsequent studies revealed that CMV is a ubiquitous agent with diverse clinical manifestations in all age groups (Weller, 1971). As new knowledge about CMV became generated, and as advances in medical care produced the advent of SOT and HSCT, the role of CMV in patients with altered host immune defense became recognized (Steininger, 2007). With the advent of the AIDS pandemic, the impact of CMV on patients with HIV infection also emerged as a major public health issue. CMV has been recognized as the most common viral opportunistic

infection in persons with AIDS, historically producing clinical disease in up to 40% of patients with advanced HIV infection (Chung and Teich, 1999; Fulkerson et al., 2021). Taxonomically, CMV is a member of the *Herpesviridae* family of viruses (Schleiss, 2009). It is considered to be a member of the betaherpesvirus subfamily, which also includes human herpesviruses 6A and 6B (HHV-6A, HHV-6B) and human herpesvirus 7 (HHV-7). CMV continues to stand as a major viral pathogen that compromises human health in diverse clinical settings. The virology, epidemiology, and clinical manifestations of CMV are reviewed below. Prospects for disease control offered by advances in antiviral therapy, as well as potential vaccines currently in clinical trials, are discussed.

Basic biology of CMV

As noted, CMV is a member of the *Herpesviridae* family of viruses. A common feature of these viruses is that they establish lifelong, latent infection in the human host. Episodic reactivations occur during the life-course of the infected individual. Immune suppression, whether it is conferred iatrogenically by the use of chemotherapy and/or immunomodulators in solid organ transplant (SOT) or hematopoietic stem cell transplant (HSCT) patients, or acquired through HIV infection, can lead to reactivation of latent CMV, which may cause symptomatic disease. Interesting, SARS-CoV-2 infection may be a risk factor for reactivation of CMV (Moniz et al., 2021).

CMV, similar to other members of the *Herpesviridae*, has a large, double-stranded DNA genome. CMV has the largest coding content of any Herpesvirus, and the genome encompasses > 230 kbp (Martí-Carreras and Maes, 2019). The CMV genome contains a unique long (UL) and a unique short (US) segment, and each segment is bracketed by terminal repeat sequences, allowing the formation of genome isomers that in turn promotes strain variation among clinical isolates. At least 700 open reading frames, and a number of non-coding RNAs, are transcribed by the CMV genome (Adamson and Nevels, 2020). Many CMV gene products promote evasion of the immune response (Boeckh and Geballe, 2011). As a result, naturally acquired immunity after infection does not confer lifelong protection against re-infection (Britt, 2017), an observation that greatly complicates CMV vaccine design.

The CMV replication cycle utilizes a coordinated, sequential expression of three families of viral transcripts: the so-called immediate early (IE), early, and late genes. IE mRNA is transcribed concomitantly with the initiation of infection, and the encoded IE proteins regulate expression of both host and viral genes. The IE promoter is also of interest, since it is one of the most potent promoters encountered in eucaryotic cell biology (Stinski and Isomura, 2008), and it has been employed in many commercial settings (such as in construction of recombinant plasmids and cell culture expression systems) that require robust transcription. CMV early gene products include DNA replication proteins and structural proteins; this is the stage of the viral life cycle that has been targeted by most licensed antiviral therapies (reviewed below). Finally, the late mRNAs are typically transcribed at more advanced time points post-infection (~72 h) and these gene products include structural proteins and other proteins involved in virion assembly and egress.

The CMV virus particle consists of three components: the capsid; the tegument layer; and the outer lipid bilayer envelope (Fig. 1). The capsid consists of 162 capsomere protein subunits that are oriented in icosahedral symmetry. The viral genomic DNA is surrounded and enveloped by the capsid proteins (the DNA/protein complexes are hence referred to as the nucleocapsid). The nucleocapsid is surrounded by the tegument layer, which contains important structural proteins, including phosphoproteins important in viral pathogenesis and immunity. One such protein, a 65-kilodalton (kDa) phosphoprotein referred to as pp65, is an important target of host cell-mediated immunity, and is a subunit vaccine candidate currently in clinical trials (Schleiss et al., 2017). The envelope surrounds the tegument. It is a typical phospholipid bilayer, as is characteristically found in other enveloped viruses. There are several virally-encoded glycoproteins, including the gB complex, the gM/gN complex, the gH/gL/gO trimer complex, and a pentameric complex consisting of proteins gH/gL/UL128, 130, and 131. These proteins are important in receptor-ligand interactions that mediate binding and entry of CMV into host cells. The proteins also elicit the virus-neutralizing antibodies that are found in CMV-seropositive individuals, and hence are vaccine candidates (discussed below).

Epidemiology of CMV transmission

CMV is transmitted by body fluids (blood, urine, breast milk, saliva, and genitourinary tract secretions) and acquisition of infection typically requires intimate contact. Modes of transmission include sexual transmission, breast-feeding, blood transfusion, and intimate household contact with secretions. CMV infection can also be acquired via solid organ transplantation. Health care providers do not appear to be at enhanced risk for acquisition of CMV (Dworsky et al., 1983). Although most individuals are eventually infected during the life-course, there is considerable variability in the age-specific seroprevalence from population to population globally. Race, ethnicity, and socio-economic factors impact age-specific seroprevalence. In the US, the overall age-adjusted seroprevalence of CMV is 50.4% (assessed for ages 6–49 years), with higher rates noted in non-Hispanic black and Mexican-American children, compared with non-Hispanic white children (Bate et al., 2010). CMV seropositivity in this study was associated with older age, being female, foreign birthplace, low household income, higher rates of household crowding, and low household education level. For children under five in the US, in whom infection is often driven by toddler-to-toddler transmission among attendees in group childcare, the seroprevalence is approximately one-in-three, (Lanzieri et al., 2021). Globally, a CMV seroprevalence rate of approximately 80% has been estimated (Zuhair et al., 2019). This study identified that the highest rates of seropositivity were observed in the developing world, particularly in the Eastern Mediterranean region, whereas lower rates (~65%)

Fig. 1 HCMV virion demonstrating key envelope glycoproteins and glycoprotein complexes important in protective immunity that stand as potential subunit vaccine candidates. Viral envelope, tegument, and nucleocapsid proteins are indicated. Glycoprotein complexes are labeled; see text for additional details.

were noted in Europe. Peaks in CMV transmission and acquisition of infection are noted in young children, particularly in association with group day care attendance, and in adolescence, associated with sexual transmission. Infants often acquire CMV infection, usually asymptotically, from breast-feeding, since CMV seropositive mothers will typically shed virus in breast milk (Schleiss, 2006).

As noted above, the CMV genome has, during the course of co-evolution with the human host, transduced a number of immune modulation and immune evasion genes from the host genome (Boeckh and Geballe, 2011). These gene products interfere with the establishment of permanent immunity following infection. Thus, re-infections with new strains of CMV can occur. Past infection does not protect against maternal re-infection during pregnancy, and, counter-intuitively, the majority of cases of congenital CMV transmission globally appear to occur in the setting of re-infection of women with preconception immunity (Britt, 2017). Primary CMV infection during pregnancy is more likely to lead to transmission to the fetus than maternal reinfection, but fetal transmission with long-term sequelae can occur by either mechanism (Permar et al., 2018). The overall prevalence of congenital CMV transmission in the US is 0.65% (Kenneson and Cannon, 2007).

Clinical manifestations of CMV infection

Most CMV infections are not clinically recognized in immunocompetent individuals. Occasionally, CMV can cause a mononucleosis syndrome clinically indistinguishable from infection with Epstein-Barr virus (Taylor, 2003). In SOT and HSCT patients, CMV can cause a variety of clinical syndromes, including a viral sepsis syndrome characterized by viremia and constitutional symptoms; pneumonia; enteritis; hepatitis; and central nervous system pathologies including encephalitis and retinitis. A risk for CMV disease following SOT can be observed both as a consequence of re-activation of latent infection in the transplant recipient, as well as acquisition of CMV from the transplanted organ itself. In HSCT patients, the greatest risk for CMV disease is in the seropositive transplant recipient. The advent of effective anti-CMV antivirals (reviewed below) has decreased the risk of serious CMV disease in the transplant setting. In addition, highly active anti-retroviral therapy (HAART) against HIV has, by reconstituting cellular immunity, had a major impact on opportunistic CMV infections in HIV-positive patients. However, in regions of the world where HAART therapy is less available, active CMV infection is an important risk factor for adverse outcomes related to other opportunistic infections, including *Cryptococcus neoformans* (Skipper et al., 2020). In the pre-HAART era, CMV was a significant cause of sight-threatening retinal infection (CMV retinitis) in patients with HIV infection (Munro et al., 2019).

In infants with congenital CMV, a wide range of signs and symptoms may be encountered, ranging from completely asymptomatic infection to severe, multi-organ system disease (also known as cytomegalic inclusion disease or CID). The likelihood of symptomatic disease depends both on whether the maternal CMV infection is a primary or recurrent infection (Permar et al., 2018) and on the timing of fetal infection, since most sequelae from congenital CMV occur in the context of first-trimester fetal infections (Chatzakis et al., 2020). Signs and symptoms of symptomatic congenital CMV infection are noted in Table 1. At birth, babies with

Table 1 Clinical manifestations of congenital cytomegalovirus infection.

<i>Clinical manifestations</i>	<i>Potential laboratory and imaging findings</i>
• Small for gestational age • Premature birth • Neurological findings ◦ Seizures ◦ Hypotonia ◦ Microcephaly ◦ Neuronal migration defects ◦ Hearing loss/failed newborn hearing screen ◦ Retinal disease (chorioretinitis) • Hepatomegaly • Splenomegaly • Petechiae • Purpura	• Hematologic abnormalities ◦ Low platelet count ◦ Hemolysis ◦ Low white blood cell count • Hepatic abnormalities ◦ Transaminase elevation (hepatitis) ◦ Hyperbilirubinemia • Cerebral-spinal fluid abnormalities • Brain imaging abnormalities ◦ Enlarged ventricles ◦ Calcifications surrounding the ventricles ◦ Neuronal migration defects • Audiological abnormalities ◦ Brainstem auditory evoked response (ABR) ◦ Otoacoustic emissions (OAE)

CID may manifest with neurological signs and symptoms, rashes (including petechiae and purpura), neurological abnormalities, enlargement of the liver (hepatomegaly) and/or spleen (splenomegaly), and jaundice. Laboratory abnormalities can include low platelet count, elevated bilirubin, and liver function test elevation. The most important long-term sequela of congenital CMV is sensorineural hearing loss. Importantly, this may occur even in otherwise-asymptomatic infants (Rawlinson et al., 2017), and infants with congenital CMV may go on to have hearing loss even if the newborn hearing screen is passed in the nursery at birth. This fact provides impetus for universal newborn screening programs for identification of congenital CMV, even in asymptomatic newborns (Dollard et al., 2021) who could benefit from serial audiological monitoring in infancy and early childhood, as well as neurodevelopmental assessments.

Another patient group at risk for CMV disease is the extremely low birthweight (ELBW) population of premature infants (Osterholm and Schleiss, 2020). Although such infections were formerly acquired from blood transfusions, improvements in leukofiltration in blood from blood banks has made this rare. Almost all such infections are acquired from breast milk. Short-term manifestations include pneumonia, thrombocytopenia, and CMV sepsis syndrome. Whether such infections lead to any long-term disabilities, such as sensorineural hearing loss, requires additional investigation.

CMV diagnostics

For decades, the mainstay of CMV diagnosis was identification of the virus in cell culture. However, culture is laborious and time-consuming, and results were seldom available in a rapid enough turn-around time to impact clinical decision-making. Today, molecular diagnosis through PCR is the preferred approach for identification of virus (Ross et al., 2011). Appropriate substrates for PCR amplification include whole blood, plasma, urine, saliva, and bronchoalveolar lavage fluid. Serologies are also available to evaluate patients for the presence or absence of CMV antibodies. Since the seroprevalence of CMV is very high in most populations, serological assays are seldom of value in the setting of acute CMV disease, where demonstration of virus is preferable. However, serological strategies are useful in guiding and counseling young women of child-bearing age. Serological screening during pregnancy is gaining acceptance (Seror et al., 2021), and may help reduce maternal-fetal transmission of CMV, particularly in CMV seronegative women who can be counseled about exposure sources to avoid during pregnancy (Schaefer et al., 2020). Serological screening is also important for donor/recipient pairs, both for living-related SOT and for HSCT patients, in order to gauge the risk of CMV infection post-transplantation and to engage in appropriate transplant planning.

Antiviral treatments targeting CMV

A number of licensed antivirals are available for treatment of CMV infection (Kotton, 2019). Most of these agents target viral DNA replication (ganciclovir, foscarnet, cidofovir). An oral prodrug of ganciclovir, valganciclovir, is also licensed and available. A recently licensed agent, letermovir, targets a later stage in the viral life-cycle, namely, the cleavage of concatemeric end-to-end viral genomes (generated during DNA replication) into individual unit length genomes for packaging into virions. Antiviral therapy for CMV is reserved for a few clinical scenarios. In the SOT and HSCT setting, antiviral agents are commonly used either as prophylaxis in the post-transplant window, toward the goal of preventing CMV disease, or as a “pre-emptive” therapy, with initiation of treatment triggered (typically) by a positive PCR test on plasma identified during routine post-transplantation laboratory surveillance studies.

For HSCT and SOT patients with CMV disease (pneumonitis, colitis, viral sepsis syndrome), antivirals are also indicated. Antiviral therapy for CMV is also indicated in HIV patients with retinitis and serious end-organ disease (pneumonitis, colitis). For congenital infection, treatment is recommended for infants with symptoms at birth, and consists of 6 months of oral valganciclovir (Rawlinson et al., 2017).

Administration of a polyclonal, high-titer CMV antibody derived from CMV-seropositive donors, Cytogam®, has been used for decades to help ameliorate the severity of CMV disease in SOT, HSCT, and ELBW premature infants. The use of this and other antibodies has been advocated in pregnant women who have evidence of primary CMV infection, toward the goal of preventing fetal transmission. However, a recent randomized controlled trial in pregnant subjects failed to demonstrate efficacy of this intervention in preventing maternal-fetal transmission (Hughes et al., 2021).

CMV vaccines

In principle, a CMV vaccine could be deployed in any of a number of settings: a universal vaccine administered in early childhood; a vaccine targeting young women of child-bearing age (toward the goal of preventing congenital transmission); or a vaccine for patients anticipating SOT or HSCT (aiming at the goal of reducing the risk of CMV disease under the immunosuppressive conditions of transplantation). These potential indications are not mutually exclusive, although the correlates of protective immunity may be different for a HSCT or SOT patient than those for a pregnant woman.

CMV vaccines that have been tested in clinical trials include live, attenuated vaccines; subunit vaccines based on recombinant proteins shown to be important in protective immunity (Fig. 1); and subunit vaccines in which the gene products of interest are expressed either in the context of DNA or RNA vaccination (Anderholm et al., 2016). So-called “vectored” vaccines, in which the immunogen is expressed in the context of a recombinant vector (such as adenovirus or vesicular stomatitis virus), are also under evaluation. Such a “vectored” vaccine approach has been successful in the development of the Ad26.CoV2.S vaccine, in which the COVID Spike protein was expressed via an adenovirus 26 vector (Corchado-Garcia et al., 2021). The Institute of Medicine has identified a CMV vaccine targeting prevention of congenital CMV infection as a “Level 1” priority for new vaccine development. Given that congenital CMV is the single most common infectious disease producing disability in newborns, acceleration of vaccine development is a high priority.

Research priorities and future directions

Much remains to be learned about the biology of CMV as well as its impact on human health. CMV has been linked to human malignancies, such as glioblastoma multiforme (Söderberg-Nauclér, 2006), and although such associations remain unproven, further studies are warranted. CMV has also been implicated in immunosenescence. Thus, the benefits of a putative CMV vaccine may extend far beyond women of reproductive age or SOT/HSCT transplant recipients. More knowledge is needed about the correlates of protective immunity, and this in turn can help drive novel vaccine and immunotherapy strategies. For women of reproductive age and care providers, greater knowledge and awareness is needed about the impact of congenital CMV on neurodevelopment and hearing. Legislative efforts to implement newborn screening are underway in many states in the US (Schleiss, 2018) and these efforts can help promote early intervention and therapies for infants, toward the goal of improving child health.

Adenoviruses in the context of clinical, applied and basic sciences

Adenoviruses (AdVs) were first isolated from human adenoid tissues in 1953 (Rowe et al., 1953). They were soon thereafter recognized as ubiquitous infectious agents implicated in diseases such as acute respiratory infections, keratoconjunctivitis and gastroenteritis (Ghebremedhin, 2014). Human AdVs (HAdVs) comprise seven species (A-G) and species B, C, D and E are endemic in the general population and cause about 5–7% of acute respiratory diseases in infants. However, these viruses can cause more severe health problems, like pneumonia or even death in immunocompromised patients, and recently severe outbreaks have been reported in Asia, Europe and in the United States (Coleman et al., 2020; Mennechet et al., 2019; Kajon et al., 2019). Adenoviruses are considered DNA tumor viruses. Although HAdV have not been shown to cause cancer in humans, the HAdV type 12 (HAdV12) was shown to induce malignant tumors in laboratory rodents making HAdVs a prominent model of tumor virology (Trentin et al., 1962). Additionally, HAdVD types 36 and 37 have been recently proposed to be etiological factors of obesity, since they have been associated with the altered differentiation and proliferation of pre-adipocytes (Esposito et al., 2012). Although there is an effective vaccine against HAdVB7 and HAdVE4, this vaccine is restricted to US military recruits and not available to the general public (Gray, 2020).

Their ability to infect multiple cellular types (broad tropism), including post-mitotic cells, the relative ease with which their genome can be manipulated and the possibility to generate high viral titers, have made AdVs one of the most commonly used systems for the design and development of candidate vectors for gene therapy and combined anti-cancer therapies (Wold and Toth, 2013; Zhang et al., 2018). Moreover, since adenoviruses induce an effective innate and adaptive immune response, both cellular and humoral, AdVs are also used for vaccine development, the recent SARS-CoV2 and Ebola virus vaccines being two notable examples (Morris et al., 2016; Appaiahgari and Vrati, 2015; Tatsis and Ertl, 2004; Coughlan, 2020; Bliss et al., 2020).

AdVs replication in infected cells induce extensive reorganization of the intranuclear milieu, cause alterations in the host-cell gene expression program, inhibit cellular DNA replication, alter cellular metabolism and can induce cell transformation (Hodge and Scharff, 1969; Beltz and Flint, 1979; Dolph et al., 1988; Huang and Schneider, 1991; Berk, 2005). Hence, adenoviruses have been used as a model system to understand eukaryotic cellular processes, such as transcription, post-transcriptional processing, nuclear organization, cell cycle control and cell death (Bridge and Pettersson, 1995; Miller et al., 2007; Challberg and Kelly, 1979).

Taxonomy

Adenoviruses belong to the *Adenoviridae* family, which comprises more than 130 different types divided in five genera (Fields et al., 2007). The *Mastadenovirus* and *Aviadenovirus* include the types that infect mammals and fowl, respectively. The *Atadenovirus* and *Siadenovirus*, include viruses that can infect a wider spectrum of animal species; the *Atadenovirus* were named for the high content of A + T in their genomes and infect mainly reptiles, fowl and ruminants; the *Siadenovirus* were named because their genome carries a gene that encodes a sialidase and encompass viruses that can infect birds and frogs. The fifth genus, *Ichtadenovirus*, include viruses that infect fish (Davison et al., 2003). Although not yet approved, the genus *Testadenovirus* has been proposed, which includes AdVs that infect testudinoid turtles (Doszpoly et al., 2013).

Within each genus AdVs are also classified into subgroups named according to the host organism they infect and the letters of the alphabet. Human adenoviruses belong to the genus *Mastadenovirus* and are further classified into subgroups or species (A-G) on the

basis of several characteristics such as DNA sequence homology, hemagglutination properties, and oncogenicity in immunosuppressed experimental animals (Harrach et al., 2019). There are more than 100 adenovirus types assigned (Brister et al., 2019), with HAdVC2 and HAdVC5 being the prototypes, as they have been most extensively studied and most commonly used in gene therapy and other applications due to their non-oncogenic properties (Shenk, 2001).

Structure

Adenoviruses form non-enveloped particles characterized by an icosahedral capsid that contains a linear double-stranded DNA genome (dsDNA) of 26–45 kb in length. The human adenovirus species C type 5 (HAdVC5) capsid has a diameter of close to 90 nm and is composed of 11 structural proteins (Fig. 1). The protein II, commonly known as hexon, is organized in 240 trimers forming the most abundant structure of the capsid. The protein III constitutes the penton base, which is associated to protein IV, which forms the fiber spikes that protrude from the surface of each of the 12 vertices of the icosahedral particle. Associated to the inner surface of the capsid are the minor proteins IX, IIIa, VI and VIII. The underlying core is formed by proteins V, VII, Mu and the Terminal Protein (TP). Except for TP, the latter have a high content of Arginine residues and interact with the negative charges of the viral genome. The viral DNA is organized surrounding protein VII, which is the most abundant protein of the viral core (Fields et al., 2007). The TP is covalently bound to the 5' ends of the viral DNA. Additionally, approximately 10 copies of the L3 viral protease 23 K are located inside the viral particles, which are essential for the infectious cycle: the protease is required for maturation of the viral progeny by cleaving the precursors (p) pIIIa, pVI, pVIII, pVII, pMu and pTP; the viral protease also promotes the disassembly and release of the viral particle from the endosome during entry into the infected-cell (Perez-Berna et al., 2009). Moreover, few copies of IVa2, a multifunctional protein that participates both in viral DNA packaging and as a transcription factor, are present in the viral particle (Christensen et al., 2008).

Viral genome organization

The terminal sequences of the genome are inverted-terminal repeats (ITR), where the origins of replication are localized. By convention, the adenovirus genome is represented beginning with the E1A transcription unit (TU) on the left side. The E1A, E1B, IX, ML, VA RNA and E3 TU are encoded on the strand that is read from left to right, while the E4, E2 and IVa2 TU are encoded on the complementary strand and are read from right to left.

The viral genome is organized in four groups of TU that are chronologically regulated (Fig. 2). The early TU are E1A, E1B, E2, E3 and E4, while IVa2 and IX are early-delayed TU. Expression of the latter depends on initiation of viral DNA replication, as it does for the late TU, which is named Major Late (MLTU). These TU are all transcribed by the cellular RNA polymerase II (RNAPII). In addition, two viral TU, VA I and II, are transcribed by the cellular RNAPIII, which produce two small transcripts named virus-associated RNA (VA RNA I and II). Although descriptive, classification of early and late genes is not completely accurate, as early genes continue to be expressed during the late phase and the viral promoter that controls the expression of all late genes, the Major Late Promoter (MLP), is active during the early phase of infection (Bridge and Pettersson, 1995; Fessler and Young, 1998; Shaw and Ziff, 1980).

Fig. 1 Structure of a human adenovirus. Schematic representation of major and minor virion proteins within the viral particle, as well as core proteins bound to the viral dsDNA genome in human adenoviruses.

Fig. 2 Diagram of the adenovirus genome. Representation of the adenovirus dsDNA (blue bars) with the E2B-TP protein attached to the 5' ends (orange circles). The viral early (E1-E4), intermediate early (IX and IVa2) and the Major Late (ML) transcription units (TU) are depicted in different shades of green and represented by arrows. The thin dark green arrows represent the L1-L5 viral late mRNA families, which are defined by different poly (A) sites. VA RNAs, transcribed by the cellular RNA polymerase III are depicted in purple. Light gray boxes represent the coding sequences of the tripartite leader (TPL) and early and late mRNAs. The black arrows on the viral genome indicate the viral promoters.

Viral gene products

The proteins encoded in E1A are named according to the sedimentation coefficient of their encoding mRNA (e.g., 12S and 13S), and are transcriptional activators and regulators of cell cycle control mechanisms. E1A proteins interact with pRB proteins inducing the release of the cellular factor E2F, which results in the expression of cellular genes necessary to enter the S phase of the cell cycle. E1A proteins also regulate the infected-cell by regulating transcription factors that control the cell cycle and chromatin remodeling factors such as the histone acetyltransferases (HAT) CBP/p300 and PCAF, the SWI/SNF family member p400, and the histone deacetylase complex HDAC. Hence, E1A products activate transcription of cellular and viral genes and induce the infected-cell to enter S-phase to establish an optimal environment for viral DNA replication and expression.

The E1B and E3 proteins are named according to their molecular mass, e.g., E1B 55K and E3 14.5K. The proteins encoded in these TU modulate a wide variety of antiviral responses that inhibit cellular defense mechanisms, or prevent premature recognition and elimination of the infected cell by the immune system of the host organism, respectively (Fields et al., 2007; Gooding et al., 1990).

The E2 products participate directly in viral DNA replication and are named according to their function: the viral DNA polymerase (pol), the pre-terminal protein (pTP) that works as a primer, and the ssDNA-binding protein (DBP) (Hoeben and Uil, 2013). The E2 TU can be transcribed from two alternative promoters, the early and late promoters (E2E and E2L). Two major classes of transcripts, E2A and E2B, are produced by selection of two different polyadenylation signals (Chow et al., 1979; Stillman et al., 1981; Stillman, 1981). The DBP protein is encoded in E2A, while the viral pol and the pTP proteins are produced from E2B (Stillman et al., 1981; Stillman, 1981; Smart and Stillman, 1982; Tamanoi and Stillman, 1982).

The E4 proteins are designated depending on the open reading frame (ORF) of the corresponding mRNA produced by alternative splicing; unlike all other adenoviral genes, the E4 TU encodes proteins with varied and unrelated activities, such as transcription and translation regulation, splicing, selective export of viral mRNA, modulation of viral DNA replication and apoptosis (Fields et al., 2007).

The IVa2 protein participates in the encapsidation of the viral genome and also activates transcription of viral late promoters (Lutz and Keding, 1996), as does the IX product, pIX, which is a structural protein that stabilizes interactions between hexon protomers (Boulanger et al., 1979), also works as a transcriptional regulator of cellular and viral TATA box-containing promoters (Lutz et al., 1997). All but the IX viral mRNA are processed by splicing (Fields et al., 2007).

The proteins encoded in the MLTU are named by roman numerals, II to VIII, and, as described above are structural proteins or proteins that are required for the assembly of new viral particles and for the expression of viral late genes (Fields et al., 2007). The late genes from the MLTU are under the regulation of two viral promoters, the L4 (L4P) and the ML (MLP) promoters. During the transition to the late phase of infection, when viral DNA molecules begin to accumulate as a consequence of DNA replication, transcription of the early delayed TU IX and IVa2 begins (Winter and D'Halluin, 1991; Venkatesh and Chinnadurai, 1987). At this time, the L4P, localized inside the gene for L4-100K, is activated, and directs the expression of the L4-22K and 33K gene products (Morris et al., 2010). IVa2, IX and the latter two L4 proteins then induce activation of the MLP (Lutz et al., 1997; Morris and Leppard, 2009; Tribouley et al., 1994). However, the MLP is also active, albeit at a low level, early during infection producing exclusively the L1 52/55K mRNA. The main transcript produced from the MLTU is a pre-mRNA processed by selection of one of five different polyadenylation sites that determine each mRNA family (L1-L5, Fig. 2). Additionally, each mRNA is processed by alternative splicing, generating a minimum of 20 different mRNA (Fig. 3). Moreover, all viral late mRNA share a common 5' sequence of 201 bases named the tripartite leader (TPL) formed by the junction of three exons named leader 1, 2 and 3 (Fields et al., 2007).

Viral replication cycle

The adenovirus replication cycle, like other DNA viruses that replicate in the nucleus of the infected-cell, is divided by convention into an early and a late phase, separated by the onset of viral DNA replication (Fig. 3).

Early phase

The early phase commences with the interaction of the fiber protein with the host cell through the receptor CAR (Coxsackie B and Adenovirus Receptor) (Nemerow et al., 2009). CAR is a component of tight junctions of epithelial cells. After this initial interaction, the penton base interacts with integrins $\alpha_v\beta_3$ or $\alpha_v\beta_5$ with lower affinity than that of CAR-fiber (Nemerow et al., 2009). This event induces the disassembly of the fibers from the virion and subsequent endocytosis mediated by clathrins. Inside the endosome, partial disassembly of the capsid continues due to the low pH that activates the viral protease associated to the virion, releasing the penton, IIIa and hexon proteins. It is proposed that protein VI facilitates lysis of the endosome, which releases the viral core to the cytoplasm. The core then is bound to dyneins to be transported through microtubules and directed to the nuclear pore complex (NPC) (Nemerow et al., 2009). The viral DNA is then imported into the nucleus through the NPC, and viral early expression begins (Berk et al., 1979; Jones and Shenk, 1979).

During the early phase of infection, the optimal intracellular conditions necessary for efficient replication and expression of the viral genome are established: (i) induction of the host cell to enter the S phase of the cell cycle in order to provide the precursor dNTP required for viral DNA synthesis, NTP and RNA processing proteins required for viral transcription, and to activate pathways required for protein synthesis (Fields et al., 2007); (ii) inhibition of the immune response, apoptosis and other antiviral mechanisms that may otherwise block viral replication; (iii) and expression of E2 genes responsible for viral DNA replication (Flint, 1977; Kovesdi et al., 1986a,b).

Late phase

Viral genome replication

As described above, viral DNA replication represents the switch to the late phase. Viral DNA synthesis proceeds through an asymmetric strand displacement mechanism. As mentioned before, the viral genome ends contain ITRs that function as DNA replication origins. The ITRs enable viral DNA circularization by base pairing of single strands generated through displacement that is stabilized by cooperative DBP binding and multimerization (Fig. 3, inset). The resulting panhandles function as origins for replication of the displaced strand. The pre terminal protein (pTP) functions as primer for the viral pol to synthesize new DNA molecules (Fields et al., 2007). Additionally, the cellular transcription factors NFI and Oct-1 participate in viral DNA replication. These two cellular proteins bind to sequences inside the ITR, inducing the viral DNA molecule to bend, therefore facilitating displacement of the DNA strands and progression of viral DNA synthesis (Fields et al., 2007).

Selective expression of late genes

With the initial accumulation of viral DNA molecules, expression of IX and IVa2 begins, and activation of the MLP increases (Morris et al., 2010). The L4P is activated, resulting in the production of L4 22K and 33K proteins. These proteins are required to increase MLP activity resulting in the production of the rest of the late transcripts from the L2, L3, L4 and L5 families (Morris et al., 2010). The L4 22K protein promotes transcription and processing of viral late mRNA and the L4 33K protein functions as a splicing factor (Morris and Leppard, 2009). Most of the proteins encoded by viral late mRNA are structural proteins that assemble to form viral progeny (Thomas and Mathews, 1980; Ifode and Flint, 2004). Viral late mRNA are subject to a selective expression program. Synthesis of cellular mRNA continues during the infection, but their export to cytoplasm is inhibited, while viral mRNA are efficiently accumulated in the cytoplasm (Flint, 1986). Viral late mRNA are exported through the cellular Nxf1/Tap-Nxt1/p15 machinery (Yatherajam et al., 2011). In addition to selective export mechanisms, viral late mRNA translation is also selectively

Fig. 3 Schematic representation of the adenovirus replication cycle. Adhesion of adenoviral particles to susceptible and permissive cells is modulated by interaction of (1) the fiber and a receptor protein (the coxsackie-adenovirus receptor, CAR, for most human adenoviruses) and (2) between the penton base and a coreceptor (integrin $\alpha v \beta 3$ or $\alpha v \beta 5$), leading to (3) cell-entry via clathrin-mediated endocytosis. (4) Release of the partially-disassembled virus particle into the cytoplasm is facilitated by a decrease in the pH of the endosome and mediated by the structural protein VI. (5) The virus particle is transported to the nuclear pore-complex (NPC) via microtubules and dynein (6) where it is fully uncoated. (7) The viral genome together with protein VII and possibly other core proteins is imported into the cell-nucleus. Protein VII remains associated with the viral DNA during the early phase of infection (Chatterjee et al., 1986; Spector et al., 2003; Wong and Hsu, 1988). (8) Within the first hours after the viral genome is delivered into the nucleus, it is localized in close proximity to PML-nuclear bodies (PML-NBs) (turquoise and green ovals represent PML and other proteins; magenta circles represent SUMO). (9) The first viral genes to be transcribed are the VA-RNAs by the host RNA polymerase III (RPIII) and the E1A by the host RPII. (10) VA-RNAs are exported to the cytoplasm by the host exportin-5. (11) E1A mRNAs are exported via the exportin-1/CRM1 machinery where they are translated to produce the E1A proteins (dark blue cylinders). (12) E1A proteins are imported to the nucleus where they promote transcription of viral early genes. (13) Viral early mRNAs are exported to the cytoplasm to be (14) translated; some E3 mRNA are translated associated with rough endoplasmic reticulum (RER; brown circles represent the ribosomes). (15) Early viral proteins (red, green and purple cylinders) are imported into the nucleus to modulate virus host-interactions and promote viral genome replication and expression of viral late genes. The cellular nuclear architecture is remodeled, inducing for example the reorganization of PML-NBs into track-like structures by E4Orf3 (E4Orf3-tracks) and formation of early replication compartments (RCs), represented by DBP (green circles) accumulation sites, adjacent to E4Orf3-tracks, where the viral genome is localized. (16) With progression of the viral replication cycle, RCs morphology changes with formation of ring-like structures and other more complex morphologies. The onset of viral genome replication by a strand-displacement mechanism (inset) marks the transition to the late phase of the viral replication cycle. With accumulation of newly synthesized DNA molecules, expression of Iva2 and IX is induced. (17) E1A, E4Orf3, Iva2 and the cellular p53 protein then activate the L4 promoter to transcribe L4-22K and L3-33K genes. (18) L4 22K and 33K mRNAs are exported to the cytoplasm and (19) translated to produce the splicing factor 33K and the transcription activator 22K (gray cylinders). (20) These L4 proteins are imported to the nucleus to activate the expression of all the viral late genes. RCs start to coalesce. (21) Viral late mRNA are selectively and efficiently exported to the cytoplasm while most of the cellular mRNAs are retained in the nucleus. (22) Viral late mRNA-translation is facilitated by the viral L4-100K protein. (23) Viral late proteins include structural proteins (green cylinders) and proteins that help to assemble new viral particles (blue cylinders). The L4-100K acts as a chaperone for the pre-assembly of structural proteins. (24) Viral late proteins enter the nucleus and localize to late RCs and participate in capsid assembly and viral genome encapsidation. (25) Maturation of virus particles is induced by proteolytic cleavage of structural proteins by the L3-23K protease. (26) The E3 adenovirus death protein (ADP) aids in the release of the progeny virus particles via cell lysis by an unknown mechanism.

regulated. This process involves the viral protein L4 100K and the VA RNA I (Hayes et al., 1990; Schneider and Mohr, 2003; Cuesta et al., 2001; Mathews and Shenk, 1991). The L4-100K protein together with the un-translated region (UTR) of the TPL from viral late mRNA, which is complementary to the 3' end of the 18S rRNA, induce a mechanism called “ribosome shunting” which allows the 40S ribosomal subunit to be directed to the start codon (Yueh and Schneider, 1996, 2000) to efficiently and selectively produce viral proteins. Additionally, VA RNA I induce the activation of the cellular kinase PKR, which in turns induces phosphorylation of eIF2 α , thus inhibiting cap-dependent translation of cellular mRNA.

Viral assembly and release

L4 100K also aids in the assembly of hexon trimers. The viral structural proteins and proteins that participate in the assembly of viral capsids and encapsidation of the viral genome are imported to the nucleus. With accumulation of viral proteins required for the assembly and formation of viral capsids, viral progeny is produced. Maturation of viral particles is induced by cleavage of the structural precursor proteins by the viral L3 protease 23K which are then released by cell lysis. Viral replication results in production of up to 10⁵ viral particles per cell, along with an excess of structural proteins and viral DNA that are not assembled into virions.

Virus-host cell interactions

The viral early proteins encoded in the adenoviral genome, E1A, E1B, E3 and E4, as well as the non-coding VA-RNAs, either inhibit antiviral responses of the cell or modulate pathways of cell proliferation and cell death that result in the establishment of conditions that result in very efficient synthesis of viral macromolecules and progeny production.

The E1A proteins are well known to inhibit the interferon response against the infection through several mechanisms, which involve the interaction of E1A with a variety of cellular proteins. The histone acetyltransferases transcriptional co-activators p300/CBP (CREB-binding protein) interact specifically with the Signal Transducer and Activator of Transcription 1 and 2 (STAT-1 and STAT-2). E1A targets p300/CBP, competes for its interaction with STAT-1 and 2 and mediates down-regulation of transactivation by these innate response proteins (Bhattacharya et al., 1996; Zhang et al., 1996). E1A also binds to STAT-1 and impedes formation of the STAT-1-IRF1 complex, leading to inhibition of expression of LMP2 (low molecular mass polypeptide 2), a gene regulated by the heterodimer STAT-1-IRF1 that encodes a protein that participates in antigen processing (Chatterjee-Kishore et al., 2000), and therefore interferes with the presentation of viral antigens. Moreover, E1A is known to downregulate the expression of interferon stimulated genes (ISG) by binding to RuvBL1 (Olanubi et al., 2017) and hBre1 leading to inhibition of the ubiquitylation of the histone H2B at ISG loci (Fonseca et al., 2012). In addition, E1A binds FOXK1/2, DCAF7, and CtBP suppressing the expression of ISGs by IRF3 (Zemke and Berk, 2017). As described before, E1A proteins associate with the pRb protein, releasing the transcription factor E2F and inducing the cell to enter the S phase of the cell cycle. This genotoxic stimulus induces the stabilization and activation of p53 that would have as a consequence the activation of apoptosis dependent on the Bcl-2 protein family (White, 2001; Steegenga et al., 1996); however, the E1B 19K inhibits apoptosis as it interacts with the cellular pro-apoptotic proteins BAX and BAK (Han et al., 1996). The E1B 55K and E4Orf6 proteins associate with and inactivate p53, resulting in the establishment of a proliferative state in which the cell is unable to die or stop DNA synthesis. Moreover, E1B 55K and E4Orf6 associate with Cullin 5-Elonguins B, C-Rbx1 to form a ubiquitin E3 ligase that induces polyubiquitylation and degradation of multiple cellular targets, among which is p53 (Querido et al., 2001; Cardoso et al., 2008; Martin and Berk, 1998; Hidalgo et al., 2019; Ip and Dobner, 2020). Additionally, E1B 55K is a multifunctional protein that also induces the SUMOylation of p53 and its consequent relocalization to viral replication compartments (RCs, described below) in which the tumor suppressor acts as a transcription activator of the L4 promoter (Wright and Leppard, 2013).

E1B 55K is also known to repress transcription of ISGs which in turn promotes efficient formation of RCs and synthesis of viral DNA (Chahal et al., 2012). E1A associates with Ubc9, the only E2 conjugator of SUMO that has been identified, altering the SUMOylation of cellular substrates (Yousef et al., 2010). Furthermore, E4Orf3 induces SUMOylation of components of the DNA damage response (Sohn and Hearing, 2016). These activities of E1 and E4 proteins are necessary for the efficient replication of the virus, but they are also decisive for its oncogenic capacity (detailed reviews can be found in Hidalgo et al., 2019; Ip and Dobner, 2020). The E3 TU encodes seven proteins (in the HAdVC2 and HAdVC5 genomes) whose main functions are to counteract the cellular defense mechanisms, by inhibiting antigen presentation mediated by MHC—I and apoptosis mediated by TNF, TRAIL and FasL signaling (Lichtenstein et al., 2004). Moreover, the viral non-coding VA RNA I and II are known to bind and inhibit effectors of the interferon signaling like the double-stranded RNA-activated protein kinase (PKR) and the 2'-5'-oligoadenylate synthetase 1 (OAS1), and to saturate the exportin 5 pathway interfering with cellular miRNA biogenesis (Vachon and Conn, 2016). A detailed review on adenoviral mechanisms that counteract cellular antiviral mechanisms can be found in Sohn and Hearing (2019).

Like other DNA viruses that replicate in the nucleus, upon infection of the cell AdV DNA is delivered into the cell nucleus where it localizes in close proximity to PML Nuclear Bodies (PML NB) by an uncharacterized mechanism (Ishov and Maul, 1996) (Fig. 3). PML NB are nuclear compartments transiently composed not only of factors involved in DNA replication and transcription, but also in antiviral responses such as epigenetic silencing, DNA repair, cell senescence, apoptosis, and regulation of the interferon-induced antiviral response (Lallemant-Breitenbach and de The, 2010).

Adenovirus infection of permissive cells results in an extensive reorganization of the infected-cell nucleus, including nuclear components that are major constituents of nuclear domains, such as PML NB, interchromatin granules (IG), paraspeckles, Cajal bodies (CB) and nucleoli (reviewed in Ishov and Maul, 1996; Schmid et al., 2014; Hiscox, 2002; Rodrigues et al., 1996; James et al., 2010; Besse and Puvion-Dutilleul, 1995; Bridge et al., 1995) (Fig. 3). The E1A and E4ORF3 proteins induce the disruption of PML NB by

redistributing the PML proteins into “fibrous-like” tracks (Fig. 3) (Leppard and Everett, 1999). These virus-induced nuclear rearrangements lead the formation of viral Replication Compartments (RCs), viral nuclear subdomains where the viral genome replicates and viral late gene expression takes place. These virus-induced nuclear compartments also constitute a hub for regulation of virus-host cell interactions. Besides recruiting molecules necessary for viral DNA replication and expression, cellular anti-viral factors implicated in various cellular activities are also recruited to RC, which are believed to be subverted at these sites, including components of the DNA damage response (ATR, the MRN complex, RPA32, ATRIP, TopBP1 and Spc1), tumor suppressors (p53, BRCA1, PML) and cellular proteins of the innate immune response (STAT-1, PKR) (Cardoso et al., 2008; Evans and Hearing, 2005; Castillo-Villanueva et al., 2014; Blackford et al., 2008; Carson et al., 2009; Maul et al., 1998; Rosa-Calatrava et al., 2003; Sohn and Hearing, 2011; Schreiner et al., 2013). A detailed review of adenovirus RCs can be found in Hidalgo and Gonzalez (2019).

Glossary

Antiviral chemoprophylaxis Using antiviral drugs to prevent influenza.

Attenuated virus vaccine A vaccine that contains weakened live virus.

Clade A taxonomic group of organisms classified together based on homologous features traced to a common ancestor.

Inactivated virus vaccine A vaccine that consists of inactivated or “dead” virus.

Negative-strand RNA viruses A group of viruses that their single strand RNA is complementary to mRNA.

Introduction

Influenza viruses (IVs) remain a public health concern since they are very contagious and infect many people annually worldwide. IVs cause respiratory disease in humans, and their clinical presentations range from mild symptoms, such as fatigue and headache, to more severe, like respiratory failure and death (Pleschka, 2013). Influenza is more prevalent in children than adults. According to the world health organization (WHO), influenza epidemics lead to 3–5 million cases of severe illness and approximately 290,000–650,000 respiratory deaths each year (WHO, 2018). More severe strains of the IVs have caused several pandemics. The last pandemic occurred in 2009 by swine flu infection and resulted in 18,631 deaths based on the WHO report; however, the number of deaths may be 10-fold higher than the reports (Simonsen et al., 2013). Several strains of IVs can also infect animals, including pigs, chickens, marine mammals, cats, horses, and ducks (CDC, n.d.). Genetic changes occur in the IVs due to their nature, and this phenomenon may cause the formation of more severe pathogenic strains of the virus leading to the pandemic occurrence (Pleschka, 2013).

This article aims to review the characteristics and epidemiology of IVs, as well as clinical features, laboratory tests, and treatment protocols of influenza disease comprehensively.

Characteristics

Types

IVs belong to the *Orthomyxoviridae* family and are divided into four types: A, B, C, and D (Park and Ryu, 2018). Different IV types have a similar structure but different antigens (Dangi and Jain, 2012). Fig. 1 illustrates the naming system of IVs. The virus type, the place of isolation, strain ID, year of isolation, and its subtypes comprise the name of the virus (CDC, 2019f).

Fig. 1 The naming system of influenza viruses.

Influenza A virus

Influenza A virus (IAV), the most important type of IVs, belongs to *Influenza virus A* genus (MacLachlan and Dubovi, 2017). The first isolation of IAV in swine occurred in 1930, and 3 years later, the first human IAV was isolated (Institute of Medicine Forum on Microbial, 2005). IAVs have caused many epidemics and all of the flu pandemics (CDC, 2019f). They infect both animals and humans, but their natural reservoirs are wild birds. Pigs are also another common zoonotic source of the virus. IAVs are classified into different subtypes based on their two viral glycoproteins: hemagglutinin (HA) and neuraminidase (NA). To date, 18 hemagglutinin types and 11 neuraminidase types have been recognized on the surface of IAVs. Although 198 IAV subtypes are expected to exist, only 131 types have been found in nature. Currently, IAV(H1N1) and IAV(H3N2) are circulating among people and are infecting them. IAV subtypes are further divided into clades (groups) and sub-clades (subgroups). The classification into clades is based on the HA gene sequences. It should be mentioned that although clades and sub-clades differ genetically, they may have the same antigens. Different IAV subtypes have different mortality and infection rate (CDC, 2019f; Park and Ryu, 2018). Overall, IAVs have a higher rate of mutation and recombination in comparison with the other IV types (Dangi and Jain, 2012).

Influenza B virus

Influenza B virus (IBV) was isolated in 1940 for the first time and belongs to *Influenza virus B* genus. IBVs can also cause epidemics worldwide; however, less attention is given to IBVs compared to IAVs. It is believed that there is no animal reservoir for IBV, and it is limited to humans, but few studies have discovered IBV in seals (Zaraket et al., 2021; Krammer et al., 2018; Bodewes et al., 2013). There was no classification for IBVs in the past, but since the 1980s, IBVs have split into two lineages: B/Yamagata and B/Victoria. Like IAVs, IBVs have further subdivisions named clades and sub-clades. It seems that B/Victoria lineage changes more rapidly than B/Yamagata genetically (Zaraket et al., 2021; CDC, 2019f). The potency of IBVs appears to be increasing, and they may even lead to a higher mortality rate in comparison with IAVs in specific populations, such as HIV patients. The importance of IBVs should not be underestimated since they cause high morbidity and mortality (Sharma et al., 2019).

Influenza C virus

Influenza C virus (ICV) belongs to *Influenza virus C* genus and was discovered in 1947. ICVs do not cause epidemics/pandemics, and they are not classified into subtypes, but to date, six lineages have been discovered for ICV: Aichi/1/81, Yamagata/26/81, Mississippi/80, Taylor/1233/47, Sao Paulo/378/82, and Kanagawa/1/76. ICVs are found mostly in humans, but they can also infect animals, such as pigs, cattle, and dogs. ICVs infect mainly children and infants. Unfortunately, ICVs are less known (Sederdahl and Williams, 2020; CDC, 2019f; Speranskaia et al., 2012). It seems that ICVs are spread around the world, but due to their challenging isolation, they are less studied than other IV types (Matsuzaki et al., 2006).

Influenza D virus

Influenza D virus (IDV) belongs to *Influenza virus D* genus and was discovered in 2011 by isolation from pigs. IDVs have three lineages: D/swine/Oklahoma/1334/2011 (D/OK), D/bovine/Oklahoma/660/2013 (D/660), and Japanese. Cattle and pigs (mainly cattle) are reservoirs of the IDVs. IDVs are distant relatives of ICVs. Serum sample screening in humans has shown that seropositivity is more prevalent in people who had exposure to cattle (Su et al., 2017; Murakami et al., 2020). Although IDVs have not led to epidemics/pandemics yet, we should not underestimate its zoonotic potential, and more investigations are required.

Virion structure and function of viral proteins

IVs have segmented single-stranded RNA genome that is negative-sense. IAV and IBV have eight RNA segments, but ICV and IDV have seven RNA segments. The shape of the virus particle (virion) can be spherical with a diameter of 80–120 nm, filamentous with a length of 250 nm–30 µm and width of 80 nm, or pleomorphic. IVs have a lipid envelope that is taken from the host cell. The virus genome encodes for viral glycoproteins (HA and NA), viral nucleoprotein (NP), matrix 1 protein (M1) and matrix 2 protein (M2)–BM2 in IBV and CM2 in ICV–, RNA polymerase subunits, the nonstructural protein 1 (NS1), and nuclear export protein (NEP)/nonstructural protein 2 (NS2). Other proteins, such as PB1-F2 and PA-X, are also produced in IAVs. Ribonucleoprotein

complexes (RNPs) consist of the viral genome (RNA), which is encapsidated with NP, and viral RNA-dependent RNA polymerase complex (RdRp). This RNA polymerase complex has three subunits: basic polymerase 1 (PB1), basic polymerase 2 (PB2), and acidic polymerase (PA)/P3. Due to the similar structure of IBV and IAV, electron microscopy cannot distinguish between them. (Dadonaite et al., 2016; Bouvier and Palese, 2008; Krammer et al., 2018). In IAV and IBV, HA and NA mediate the virus entry and release, but in ICV and IDV, hemagglutinin-esterase-fusion (HEF) glycoprotein fulfills the function of both HA and NA (Sederdahl and Williams, 2020) (see Fig. 2).

The proteins encoded by each segment are shown in Table 1. PB1, a subunit of RdRp, elongates the viral RNA. It seems that the S-D-D motif forms an active site for the protein in its center. PB2 binds to the cap of the cellular pre-mRNA and leads to its cleavage by PA via its endonuclease activity (Fodor, 2013). PB1-F2 has pro-apoptotic activity. HA is one of the main surface glycoproteins and antigens, with the structure of head and stalk, in IAV and IBV that mediates the attachment and entry to the host cell. HA hemagglutinates the red blood cells during incubation with virions. NA is another surface glycoprotein that possesses sialidase activity and mediates the release of virus from the host cell. HA is four times more prevalent than NA in the envelope of the virus (Pleschka, 2013; Krammer et al., 2018). As mentioned before, HEF is the surface glycoprotein of ICV and IDV in which the function of HA and NA is combined (Sederdahl and Williams, 2020; Speranskaia et al., 2012). NP encapsidates the viral RNA and regulates the nuclear import in the host cell. M1 is the matrix protein under the lipid envelope and supports the viral shape. M1 also regulates

Fig. 2 Structure of influenza virus.

Table 1 Genes on RNA segments.

Segment	IAV	IBV	ICV	IDV
1	PB2	PB2	PB2	PB2
2	PB1	PB1	PB1	PB1
	PB-F2	–	–	–
3	PA	PA	P3	P3
4	HA	HA	HEF	HEF
5	NP	NP	NP	NP
6	NA	NA	M1	M1
	–	NB	CM2	CM2
7	M1	M1	NS1	NS1
	M2	BM2	NS2	NS2
8	NS1	NS1	–	–
	NEP	NEP		

HA, hemagglutinin; HEF, hemagglutinin-esterase-fusion; M1, matrix 1 protein; M2, matrix 2 protein; NP, nucleoprotein; NEP, nuclear export protein; NS1, nonstructural protein 1; NS2, nonstructural protein 2; NA, Neuraminidase; PB1, basic polymerase 1; PB2, basic polymerase 2; PA/P3, acidic polymerase.

the nuclear export of the RNA and interacts with RNP. M2 is an ion channel traversing the lipid membrane of the virus with a pH-dependent activity. NS1 is an interferon antagonist protein that helps to replication of the virus by inhibiting interferons. NS1 also regulates the activity of RdRp. NEP mediates the nuclear export of RNPs (Krammer et al., 2018; Pleschka, 2013; Fodor, 2013; Dangi and Jain, 2012).

Life cycle

As mentioned above, HA mediates the virus entry to the host target cells, such as epithelial cells of the human respiratory tract or epithelial cells of the intestinal tract of birds. HAs, located in the viral envelope, bind to sialic acid (neuraminic acid), which is found in some resident molecules (as a receptor) of the target cell membrane. HA from human influenza has more affinity for sialic acids with $\alpha 2,6$ linkage to the rest of their oligosaccharide, but avian influenza HA shows more affinity to $\alpha 2,3$ -linked sialic acids. After binding to the host cell, the virus becomes surrounded by an endosome, a process called endocytosis. The endosome has low pH (5–6), and M2 protein accelerates the acidification of the endosome. The low pH within the endosome leads to the fusion of the viral envelope with the endosome. This process is mediated by cleavage of the disulfide bond between HA1 and HA2 and the exposure of fusion peptide on HA2, consequently. Eventually, the fusion peptide on HA2 leads to the fusion of the viral envelope and endosomal membrane. In the meantime, M2 protein lowers the pH of the viral particle, leading to dissociation of viral RNPs from matrix proteins (M1) and release of viral RNPs to the host cell cytoplasm (Krammer et al., 2018; Allen and Ross, 2018) (see Fig. 3).

After the release of viral RNPs to the cytoplasm, they become imported to the nucleus of the host cell, mediated by nuclear localization sequences (located in NPs). Transcription and replication of viral RNA to positive-sense RNA occur in the nucleus by RdRp that is bound to the viral RNP complex. PB2 and PA cooperation cause the attachment and cleavage of 5' caps from cellular RNAs. After polyadenylation of 3' end of the RNA, the viral pre-mRNA is ready to be exported from the host cell nucleus. IVs replicate their genetic material (viral RNA) using the complementary ribonucleoprotein (cRNP) complex for transcription of negative-sense RNA. Translation of viral proteins by the host ribosomes occurs in the cytoplasm of the cell, mediated by the viral mRNA (Wu et al., 2007; Krammer et al., 2018; Allen and Ross, 2018). It should be mentioned that NS1 contributes to the translation of viral proteins and the regulation of viral gene expression. Proteins, such as PB1, PB2, PA (proteins of RNA polymerase complex), and viral NP are imported to the cell nucleus from the cytoplasm to accelerate the viral RNA synthesis, and proteins, such as HA (needs a cleavage by cellular proteases for activation), NA, and M2 that eventually take place in the viral lipid envelope, traffic from the rough endoplasmic reticulum and Golgi apparatus to the cell membrane. Specific signals on viral RNA checks the appropriate assembly of all viral parts to form a proper new virus particle. At late stages of the virus replication, M1 and NEP are

Fig. 3 The life cycle of the influenza virus. HA proteins of the influenza virus bind to cell receptors and mediate the virus entry to the host target cell. The virus becomes surrounded by the endosome. Then the viral envelope fuses with the endosome, and the released RNPs are imported to the nucleus for replication and transcription of mRNA. Viral mRNA encodes viral proteins in the cell cytoplasm. Finally, viral proteins and viral genome are assembled into new virions, and new virions are released by the contribution of NA proteins. NA, neuraminidase; HA, hemagglutinin; ER, endoplasmic reticulum; RNP, ribonucleoprotein; mRNA, messenger RNA.

exported to the cell nucleus to incorporate with viral RNPs and mediate their export to the cytoplasm of the cell with help of recycled endosomes. Finally, the budding of the virus initiates by the accumulation of M1 in the cytoplasmic side of the cell membrane, and NA cleaves the bond of HA with receptors containing sialic acid to release the virions from the cell surface (Krammer et al., 2018; Allen and Ross, 2018; Hao et al., 2020; Pleschka, 2013).

Antigenic drift and shift

Two main mechanisms of antigenic alternation in IVs are antigenic drift and antigenic shift. These events in IVs complicate the vaccine production process; therefore, the vaccines need to be updated each year (Krammer et al., 2018).

Antigenic drift refers to small mutations in the viral genome that alters the epitopes of the virus. Unlike DNA polymerase, the RdRp complex of the virus has no proofreading mechanism, leading to the accumulation of new mutations during each replication cycle. The high rate of replication and mutation accelerates the occurrence of new antigenic changes and adaptation of the virus to the host cell. Even though many of these mutations cause minor changes or disadvantageous alternations to the virus, some of the mutations introduce key conformational changes to the epitopes of HA (in the head, not in stalk) and NA (mainly HA). These changes aid the virus in escaping from the host cell's antibody-mediated immunity (Krammer et al., 2018; Kim et al., 2018; Matsuzaki et al., 2016). Antigenic drift occurs in all the IV types. It mainly occurs in IAVs, but it has a slower rate in IBVs. Antigenic drift rarely occurs in ICBVs and IDVs. It seems that the last antigenic drift in ICBVs occurred 30 years ago (Su et al., 2017; Matsuzaki et al., 2016).

The antigenic shift causes drastic changes in the genome of the IVs, and it is more prevalent in birds. Since the genome of the IVs is segmented, when a host cell is infected with two different strains of the IVs, gene reassortment can occur. The antigenic shift can take place in the host cell when two strains of IAV from the same *genus* co-infect the cell (see Fig. 4). Theoretically, 254 different combinations of segments are expected to happen; however, only a few combinations have occurred and been recognized. Some animals, such as pigs, bats, and quails are called “mixing vessels” for genetic reassortment because they can be infected by both human influenza (possess receptor for $\alpha 2-6$ -linked sialic acids) and avian influenza (possess receptor for $\alpha 2-3$ -linked sialic acids). When these different strains exchange their HA and/or NA genes, a new strain emerges from the host cell that may acquire the ability of human-to-human transmission. The antigenic shift can lead to a pandemic. Although only a limited number of pandemics have happened, no one can anticipate the time of the next pandemic (Kim et al., 2018; Ma et al., 2008; Krammer et al., 2018).

Epidemiology

IAV and IBV co-circulate among the human population and cause seasonal epidemics annually around the world. Children are more prone to infection with IVs, and the severity of the disease is higher in children and elderly individuals (>65 years old) than the rest of the population. Interestingly, children vaccination diminishes the number of the cases in the elderly population. Currently, H1N1 and H3N2 are the main IAVs circulating among the human population. Limited zoonotic transmissions to humans, including avian H5N1 and H7N9, swine H3N2, are being reported in some regions; however, human-to-human

Fig. 4 Process of the antigenic shift in influenza virus.

transmission rarely occurs with these strains (Krammer et al., 2018). Since the 1980s, IBV has spread in seasonal flu epidemics, and it appears to be more prevalent in children aged 1–10. 23% of the IV infections have been caused by IBV between 2000 and 2018 (CDC, 2019e; Zaraket et al., 2021). Most ICV infections occur during early childhood. However, several familial transmissions of ICV and outbreaks have been reported among military recruits, travelers on the Hajj pilgrimage, and healthcare workers (Sederdahl and Williams, 2020). IDV is also circulating among animals, including pigs, bovine, cattle, and small ruminants (Su et al., 2017).

Low temperature and low humidity increase the susceptibility to IV infection. Therefore, the IV epidemics are more prevalent in cold seasons, especially in winter. Approximately 42% of the influenza peaks have occurred in February between 1982 and 2018. Climate factors, such as duration of sunshine and maximum rainfall, are strongly associated with the spread of IVs (CDC, 2019e; Krammer et al., 2018).

According to the WHO, influenza epidemics lead to 3–5 million cases of severe illness and approximately 290,000–650,000 respiratory deaths each year (WHO, 2018). Additionally, based on the Centers for Disease Control and Prevention (CDC) reports, IV has infected 9.2–35.6 million cases and resulted in 140,000–710,000 hospitalizations between 2010 and 2017 in the United States (Krammer et al., 2018). Children and the elderly population, people with co-morbid diseases, pregnant women, and immunosuppressed patients are at higher risk of infection and severe illness (Krammer et al., 2018).

Based on the historical reports, 31 influenza pandemic-like events have occurred since 1580 (Lazzari and Stöhr, 2004). During the 20th century, three pandemics have occurred, and in the 21st century, we have faced one influenza pandemic (see Table 2). The first and the most severe pandemic of the 20th century occurred in 1918–19 by an A H1N1 virus (“Spanish flu”) that had genes with avian origin. A higher mortality rate was seen in under-five children, 20–40 years old population (specific characteristic of this strain), and older adults (>65 years old). H1N1 infected at least one-third of the world population and resulted in more than 50 million deaths. No availability of vaccines and antibiotics complicated control of the “Spanish flu” (CDC, 2019a; Dangi and Jain, 2012). The second pandemic of the 20th century occurred in February 1957–58 by a new IAV, H2N2, that emerged in East Asia. It is believed that “Asian flu” resulted from the genetic shift of human influenza and avian influenza in pigs. H2N2 frequently infected children aged 5–19. “Asian flu” resulted in 1.1 million worldwide. Rapid vaccination decreased the death rate of “Asian flu” in comparison with “Spanish flu” (Lina, 2008; CDC, 2019b; Dangi and Jain, 2012). In July of 1968, the third pandemic of the 20th century started in Hong Kong by a new IAV virus, H3N2 (“Hong Kong flu”). Like the “Asian flu,” H3N2 resulted from gene reassortment of human influenza and avian influenza. Approximately 1 million people died due to the H3N2 virus. Moreover, in this pandemic, rapid vaccination contributed to lower the number of deaths and cases (CDC, 2019c; Lina, 2008). To date, the only pandemic of the 21st century emerged in the United States in 2009 by a novel IAV (H1N1)pdm09, with a swine origin. The gene combination of this new virus was not recognized previously in humans or animals. However, similarities between the H1N1 virus from the 1918 pandemic and (H1N1)pdm09 were detected. Based on the CDC reports, (H1N1)pdm09 resulted in 60.8 million cases (43.3–89.3 million), 274,304 hospitalizations (195,086–402,719), and 12,469 deaths (8868–18,306) in the United States and 151,700–575,400 deaths (in the first year) worldwide. Unlike seasonal influenza, most of the deaths due to (H1N1)pdm09 occurred in people younger than 65 years of age. Due to fundamental differences between seasonal influenza and (H1N1)pdm09, vaccination with seasonal flu vaccines showed only a slight protection against (H1N1)pdm09. After November, large number of vaccines against (H1N1)pdm09 were available in the United States (CDC, 2019d; Dangi and Jain, 2012).

Host immune response and immunopathogenesis

After entering the body, the IV binds to the epithelial cells of the respiratory tract of humans and other mammals; however, in the birds, IV infects the epithelial cells of the intestinal tract (Krammer et al., 2018). It should be mentioned that several other studies have detected infection of the other cells, such as type II pneumocytes, alveolar macrophages, dendritic cells, and retinal epithelial cells with IV (Shim et al., 2017). IAV and IBV infect both the upper and lower respiratory tract, but in contrast, ICV infects only the upper respiratory tract (Su et al., 2017). Lung inflammation is the main reason for illness in influenza. The pathological changes are mainly located in the lungs, including alveolar damage with hyaline membranes, septal edema tracheitis, epithelial hyperplasia, squamous metaplasia of bronchus, necrotizing bronchiolitis, pulmonary vascular congestion, and alveolar hemorrhage (Dangi and Jain, 2012).

IV infection activates the innate immune response, followed by the humoral and cell-mediated response (adaptive immune response). The recognition of viral replication by pattern recognition receptors (PRRs), including toll-like receptors (TLRs), nod-like receptors (NLRs), and Retinoic acid Induced Gene 1 like receptor (RIG-I), initiate the innate immune response. TLR3, 7, 8, and 9

Table 2 Recent influenza pandemics.

Year	Name	Strain	Number of deaths
1918–1919	Spanish flu	H1N1	>50 million
1957–1958	Asian flu	H2N2	1.1 million
1968–1969	Hong Kong flu	H3N2	1 million
2009	Swine flu	(H1N1)pdm09	151,700–575,400 (first year)

recognize the presence of IV in the cell. Other TLRs (TLR 1, 2, 4, 5, and 6) indirectly sense the IV infection by recognizing damage associated molecular patterns (DAMPs). NLRs contribute to the formation of the inflammasome complex, leading to the cleavage of proinflammatory cytokines, s pro-interleukin (IL)1 β and pro-IL-18 and helps to virus clearance. The last member of PRRs, RIG-I is expressed in lung epithelial cells and alveolar macrophages. RIG-I activation by 5'-triphosphate viral ssRNA causes translocation of NF- κ B and/or interferon regulatory factor (IRF)3/7 to the nucleus of the cell and production of type I and III interferons, as well as proinflammatory cytokines, consequently. It seems that the production of type I interferon by the epithelial cells and alveolar macrophages plays an important role in the development of antiviral responses. The activation of PRR pathways leads to the activation of proinflammatory pathways and the production of proinflammatory cytokines, such as IL-1, -6 and -8, tumor necrosis factor (TNF- α), macrophage inflammatory protein-1 α/β (MIP-1 α/β), interferon induced protein (IP-1), etc. The recruitment of immune cells, such as neutrophils, dendritic cells (DC), monocytes, and lymphocytes into the alveolar space is mediated by the proinflammatory cytokines. The excessive activation of inflammatory pathways causes an event called "cytokine storm," which is the excessive response against the IV and increases the patient's mortality. The reason for the poor prognosis in the cytokine storm is the high production of proteases, oxygen, and reactive nitrogen species due to uncontrolled activation of immune cells, leading to tissue damage (Tavares et al., 2017; Sun et al., 2018). Approximately 7 days after IV infection, CD4⁺ and CD8⁺ T cells and B cells become activated. CD4⁺ T cells regulate differentiation of other immune cells and produce cytokines, and CD8⁺ T cells destroy the infected cells with granzymes and perforin. In addition, they express FASL that leads to the apoptosis of the infected cells. B cells secrete antibodies that protect the body against secondary IV infection and neutralize the viruses (Tavares et al., 2017; Zhang et al., 2020). Natural killer (NK) cells also lysis the infected cells via the interaction of NKp46 receptors and HA proteins (Zhang et al., 2020).

The IVs have several ways to neutralize the immune system of their hosts. NS1 protein inhibits type I interferon production as the result of inhibiting IRF3 activation. NS1 protein also binds to the DNA of the host cell and inhibits the transcription of antiviral genes. The failure of interferon responses (due to NS1 protein) and accumulation of viral RNA in the cell activate the apoptotic pathways of the host cell (Shim et al., 2017). Besides, autophagy is another host defense mechanism in response to IV infection (Zhang et al., 2020). NA proteins of IV block the NKp46 receptors and contribute to the escape of HA protein recognition by these receptors. Moreover, HA proteins accelerate the degradation of interferon receptors, and another protein, PB-2, also contributes to interferon antagonism (Chen et al., 2018).

Clinical features

Transmission

The IVs spread among humans mainly through respiratory routes. Coughing, talking, and sneezing of an infected individual generate large droplets (diameter >5 μ m) and small particle aerosols containing virus particles. Large droplets are only able to travel a short distance (approximately 6 ft); therefore, infection through large droplets needs close contact between at least two individuals. But small particle aerosols can be transmitted over longer distances and remains for a longer time in the air. In addition to respiratory routes, contaminated surfaces with respiratory secretions of infected individuals are another route for transmission of IV (Krammer et al., 2018; UpToDate, 2020).

Fecal-fecal, fecal-oral, or fecal-respiratory routes are the main routes for transmitting IV between wild birds. For the transmission of IV in swine, pig-to-pig contact is required. Newly formed IVs in swine (with an avian origin) spread via airborne transmission between animals after establishment in the mammals. Animal-to-human transmission of IVs occurs through direct contact or contaminated environments (Krammer et al., 2018; WHO, n.d.; Webster, 1997).

Each IV types have a specific attack rate. The attack rate of the seasonal influenza is 5–10% in the adults and 20–30% in the children. The attack rate of IAV and IBV in the adults is approximately 2.32% and 0.59%, respectively, but the attack rates for IAV and IBV are higher in the children, 12.27% for IAV and 5.5% for IBV (Park and Ryu, 2018).

Clinical manifestations

The incubation period of IVs is approximately 1–4 days, and the virus has a high rate of transmissibility in its incubation period. The severity of clinical presentations depends on several factors, such as age and previous exposure to the virus. The initial unspecific symptoms have a sudden onset and include fever, chill, myalgia, headache, malaise, and anorexia. Respiratory symptoms are sore throat, cough (usually dry), rhinitis, and nasal obstruction (Krammer et al., 2018; UpToDate, 2020). Infection in elderly patients and patients with weak immunity may have a mild presentation (due to lower secretion of cytokines), but it may result in severe low respiratory tract illnesses. Lack of energy, confusion, and fever without respiratory symptoms may be the clinical manifestations in elderly patients (Krammer et al., 2018). Influenza is usually self-limited, and the patient recovers from the illness within a week (Dangi and Jain, 2012). However, some symptoms, such as cough, may remain for several weeks. The leukocyte count is usually normal or low in the early phase of the disease, but it may become higher in the late stages of the disease (UpToDate, 2020).

As mentioned above, influenza is usually uncomplicated and self-limited, but IV can cause severe respiratory illnesses and complications in the infected patients. Otitis media occur in less than 50% of the infected children 4 days after the symptom onset. Patients with specific medical conditions, such as liver disorders, kidney disorders, blood disorders, heart diseases, etc., may have complicated influenza. Pneumonia is a common complication of influenza in patients with specific medical conditions and

low-risk children under 2 years. Influenza pneumonia is usually mild but has a worse prognosis in hospitalized patients (UpToDate, 2020). Rapid progression of fever, cyanosis and shortness of breath are among the clinical presentations of influenza pneumonia (Krammer et al., 2018). The radiologic findings of influenza pneumonia are ground-glass opacities, centrilobular nodules, branching linear opacities, and consolidation. The infiltration in the lung can be both interstitial and alveolar (Oikonomou et al., 2003; UpToDate, 2020). Other reported complications of influenza are laryngotracheitis or tracheobronchitis, acute myositis (mostly in IBV), myocarditis, pericarditis, febrile seizures, aseptic meningitis, Guillain-Barré syndrome, postinfectious encephalitis, exacerbation of pulmonary diseases (such as asthma), plastic bronchitis, and acute respiratory distress syndrome (ARDS)-one of the leading causes of death in infected patients. ARDS in patients with influenza is the excessive and persistent inflammatory response of the body against the IV (UpToDate, 2020; Khanmohammadi et al., 2021).

Detection methods

Several diagnostic tests can be conducted to recognize IV infection, but they are not performed on all the suspected patients. Viral tissue cell culture, rapid cell culture, reverse transcription-polymerase chain reaction (RT-PCR), rapid antigen test, rapid molecular assay, and immunofluorescence, direct (DFA) or indirect (IFA) fluorescent antibody staining are the available diagnostic tests for IV (CDC, 2020b; Ravina et al., 2020) (see Table 3).

Viral cultures are the most traditional and gold standard test for IV detection. Respiratory specimens, such as nasopharyngeal swabs, throat swabs, and sputum, are used for viral cultures. The result of the test has a high specificity (>95%), and more than 3 days (up to 10 days) are required for the preparation of the results. Viral culture tests are mostly performed in outbreaks to determine the IAV subtypes as well as IAV and IBV strains. They are also used for recognizing the IV strains for the vaccines of the next years. Besides, behavioral and morphological changes, like the cytopathic effect of the IV, can be detected in viral cultures, enabling surveillance of antiviral sensitivity and antigenic drift. Detection of ICV in cell culture is challenging since they have a weak cytopathic effect (Ravina et al., 2020; CDC, 2020b; Dziąbowska et al., 2018; Krammer et al., 2018; Sederdahl and Williams, 2020).

Immunofluorescence assays are used to detect viral antigens. This method has a high specificity and moderate sensitivity, and 2–4 h are needed to prepare the result. Both DFA (easier and shorter response time) and IFA can be used for IAV and IBV detection, but they are unable to recognize the IAV subtype. Epithelial cells from the respiratory specimens are stained with antibodies (produced in animals) that are labeled with fluorescent; then, the epithelial cells are observed under a fluorescent microscope (CDC, 2020b; Dziąbowska et al., 2018).

Rapid influenza diagnostic tests (RIDTs) detect the viral antigens (mostly NP) within 15 min. Different types of RIDTs with the ability to detect only IAV or both IAV and IBV with/without distinguishing between them are available; however, RIDTs cannot distinguish between IAV subtypes. Respiratory specimens, such as nasopharyngeal or throat swabs, are used in RIDTs. RIDTs have low sensitivity, but they have a low rate of false-positive results; however, false-positive and false-negative results should be considered in influenza outbreaks. Different RIDTs have different sensitivities and specificities. The fast response and easy

Table 3 Detection methods for influenza virus.

Method	Test time	Specimens	Advantages	Disadvantages
Viral culture	3–10 days	Respiratory Specimen	- Moderately high sensitivity and highest specificity - Enables public health surveillance, and characterization of virus - Distinguishes between IAV and IBV, and IAV strains	- Slow - Lower sensitivity than RT-PCR - Needs highly skilled staff
Immunofluorescence	2–4 h		- Moderately high sensitivity and high specificity - Distinguishes between IAV and IBV	Prone to false negative results in outbreaks
Rapid influenza diagnostic tests	<15 min		- Fast - Moderate sensitivity and high specificity - Low cost	Prone to false negative results in outbreaks
RT-PCR	1–8 h		- High sensitivity and specificity - Distinguishes between IAV and IBV, and IAV strains - Can be multiplexed	- Expensive - More prone to false positive results than culture
Rapid molecular assays	15–30 min		- High sensitivity and specificity - Distinguishes between IAV and IBV - Fast	Expensive
Serological assays	–	Serum	Public health investigations and research purposes	- Need paired samples - Unsatisfactory sensitivity - Low availability

RT-PCR, reverse transcription polymerase chain reaction; IAV, influenza A virus; IBV, influenza B virus.

conduction are among the advantages of RIDTs. The results of the RIDTs are more accurate in children than adults (Dziąbowska et al., 2018; CDC, 2020b; Ravina et al., 2020).

RT-PCR detects the presence of IV in the respiratory specimens with high sensitivity and specificity, but it is an expensive method. 1–8 h are required for the preparation of the result of the test. In RT-PCR, viral RNA is converted to complementary DNA (cDNA), then the segments are amplified by random hexamers. Matrix gene amplification can be performed to determine the IV types, and RT-PCR containing specific primers for HA gene are also used for IAV subtyping. Several RT-PCR and new real-time PCR is developed for distinguishing between H1 strains. In addition, multiplex RT-PCR can recognize several viruses in the sample by combining multiple primers sets (CDC, 2020b; Dziąbowska et al., 2018; Ravina et al., 2020). RT-PCR is an appropriate method for IDV and ICV detection (Dziąbowska et al., 2018; Sederdahl and Williams, 2020).

Rapid molecular assays are based on isothermal nucleic acid amplification, and their results are ready within 15 min. The results have high specificity and sensitivity. Another method used in the rapid molecular assay is RT-PCR, which prepares the results in 20 min. Some of these tests can distinguish between IAV and IBV and also determine some of the IAV subtypes. It should be mentioned that upper respiratory tract specimens are mostly tested in rapid molecular assays, and they are not approved for lower respiratory tract specimens (CDC, 2020b; Dziąbowska et al., 2018; Ravina et al., 2020).

Serological assays, such as enzyme-linked immunosorbent assay (ELISA), single radial hemolysis (SRH), complement fixation assay, hemagglutination inhibition assay (HAI), western blotting, etc. are based on the detection of antibodies against viral antigens with an unsatisfactory sensitivity. Serological tests are not recommended since they need paired samples (first one at the beginning of infection and second one 2–4 weeks after); therefore, they are only available for public health investigations and research purposes. The serological assays use several techniques, such as hemagglutination inhibition by the increase in the antibody level, the measurement of hemolysis areas (related to antibody level), the ability for virus neutralization, and antigen-antibody interaction to recognize the antibodies against viral antigens (Dziąbowska et al., 2018; CDC, 2020b).

Other methods, such as biosensors, which detect based on recognizing biological analytes, can be used for IV detection (Ravina et al., 2020).

Treatment protocols

Symptomatic treatment and antiviral drugs are available for Influenza treatment. Most of the infected individuals do not require antiviral treatment. In mild illnesses, staying at home, hand washing, minimizing contact with other people and administering over-the-counter medications contribute to the patient's recovery. However, for the hospitalized patients, patients with severe illness, and patients at higher risk of complications, antiviral treatment is required (see Table 4) (CDC, 2021a). People with special medical conditions, elderly patients (≥ 65 years), under-five children, pregnant women, etc., are among the individuals at higher risk of complications. Antiviral drugs are used for both treatment and prevention (UpToDate, 2021b).

Neuraminidase inhibitors, oseltamivir (oral), zanamivir (the first drug in this class, inhaled as powder), and peramivir (intravenous) block the enzyme activity of NA proteins and inhibit the release of progeny influenza virus from the infected host cells. These drugs apply their effect with the contribution of their structure as a sialic acid analog. Both IAV and IBV can be targeted with these drugs. NA inhibitors should be used at the early stages of the disease since they act at the viral replication stages. Reduced viral shedding and duration of symptoms result from the administration of NA inhibitors. Oseltamivir and zanamivir are also recommended for chemoprophylaxis (UpToDate, 2021b; CDC, 2021a).

Baloxavir marboxil (oral) is another antiviral drug that inhibits cap-dependent endonuclease activity of PA protein and subsequent inhibition of mRNA synthesis. Both IAV and IBV are targeted by baloxavir. This drug should be administrated within 2 days after the onset of the disease and can also be used for prevention. It should be mentioned that baloxavir is mainly used in uncomplicated influenza, and data for its efficacy in severe forms of the disease is limited (CDC, 2021a; UpToDate, 2021b). A study examined the efficacy of baloxavir against all IV types, A, B, C, and D, and the results showed that baloxavir could be the first therapeutic option against ICV (Mishin et al., 2019).

Table 4 Influenza medications.

<i>Antiviral agent</i>	<i>Mechanism of action</i>	<i>Affected influenza types</i>	<i>Chemoprophylaxis</i>	<i>Route of administration</i>
Oseltamivir	Neuraminidase inhibitor	IAV and IBV	+	Oral
Zanamivir			+	Inhaled
Peramivir			–	Intravenous
Baloxavir marboxil	cap-dependent endonuclease inhibitor	IAV and IBV	+	Oral
Amantadine	M2 ion channel inhibitor	IAV	N/A	Oral
Rimantadine			N/A	Oral

IAV, influenza A virus; IBV, influenza B virus; N/A, not available.

Adamantanes, amantadine (oral) and rimantadine (oral), inhibit M2 ion channel protein and act only against IAV. They can shorten the duration of symptoms. Adamantanes are no longer recommended for influenza treatment since IAVs are highly resistant to them (UpToDate, 2021b). IAV H3N2 and IAV H1N1 that are currently circulating as seasonal influenza, are also resistant against the adamantanes (UpToDate, 2021b; CDC, 2021a).

Drug resistance in IVs is a major concern of the healthcare system. Although the level of drug resistance is low for baloxavir and NA inhibitors, but drug-resistant viruses can emerge in children, hospitalized patients (due to longer duration of illness), and immunocompromised patients. It seems that using drug cocktails in the future is required to fight against drug resistance in IVs. Besides, new NA inhibitors are being examined in several clinical trials to introduce new antiviral drugs (Krammer et al., 2018).

Vaccination

Effective vaccination against IVs could contribute to overcoming the outbreaks. The first influenza vaccine was inactivated influenza A virus, developed in the 1940s. However, new IV strains were discovered, and this vaccine lost its effectiveness quickly (Krammer et al., 2018). Influenza vaccines need annual updates since the circulating strains of each outbreak are different (Dangi and Jain, 2012). For developing the inactivated viruses, the master high-growth IV (A/Puerto Rico/8/1934) and the circulating strain of IV co-infect the embryonated chicken eggs. It is noticeable that further developments in vaccine production processes enabled using mammalian cell cultures instead of embryonated chicken eggs. After the occurrence of gene reassortment, the new virus that contains NA and HA genes from the circulating strains and internal protein genes of the master high-growth virus is selected and amplified. The virus vaccine becomes inactivated with alkylating reagents. Adding adjuvants to the inactivated vaccines increases the efficiency. It should be mentioned that new technologies have developed new recombinant vaccines with inactivated viruses using DNA-recombinant technology and cell-cultures (IV and egg free) (Krammer et al., 2018; CDC, 2020a, 2021c).

Currently, there are two main types of influenza vaccines: flu shot vaccines and nasal spray vaccines. The flu shot vaccine contains the inactivated viruses and is injected intramuscularly. Trivalent flu vaccines contain IAV H1N1 and H3N2 plus an IBV strain, but quadrivalent flu vaccines contain two IAV strains, H1N1 and H3N2, and two IBV strains. Flu shots are approved for individuals older than 6 months. Severe allergic reaction to the vaccine components is the main contraindication of flu shots (CDC, 2021c; UpToDate, 2021a). The nasal spray vaccine or live attenuated influenza vaccine (LAIV) is another influenza vaccine containing two IAV strains (H1N1 and H3N2) plus two IBV strains. LAIV can be administered in individuals aged 2–49 years. Pregnancy, having specific medical conditions, having an allergy to any vaccine components, etc., are among the contraindications of LAIV (CDC, 2021b; UpToDate, 2021a).

The annual influenza vaccination is recommended for all individuals more than 6 months of age; however, when vaccine supply is inadequate, a specific group of people has a higher priority. Immunocompromised patients, individuals more than 59 years of age, patients with chronic disorders, such as asthma, metabolic, pulmonary, renal, hepatic, or neurologic disorders, native Americans, extremely obese people, pregnant women, and residents of nursing homes have a higher priority for influenza vaccinations (UpToDate, 2021a).

Influenza vaccines have various efficiencies from season to season, depending on the similarity of circulating viruses and vaccine viruses. When the circulating viruses and vaccine viruses have a high similarity, an individual's age and health status are the indicator factors of vaccine efficiency (CDC, 2021c). Common side effects of the influenza vaccine are headache, fever, nausea, muscle aches, pain in the injection site, and fatigue. However, severe side effects, such as serious allergic reactions to vaccines and Guillain-Barre syndrome, rarely occur due to the influenza vaccine (CDC, 2021c).

Conclusion

IVs have been challenging humans for more than 100 years. The ability of IV to change its genetic material and circulate in both human and animals, complicate its management for the healthcare system and government. The epidemiology and burden of influenza show the important effects of this virus on human life. Influenza is a global health concern and needs global preparedness. Despite the progress in managing influenza outbreaks, inadequate attention is given to the population at higher risk of severe illness and even death. No one knows the time of the next influenza pandemic since new strains can emerge at any moment and consequently lead to many deaths. Thus, the world should prepare itself for the management of IV. The efficacy of influenza vaccines currently available is not optimal, and mutations in circulating vaccines can highly affect it. The protection provided by vaccines only lasts for one flu season. Moreover, drug resistance is another concern of the healthcare system for treating influenza. Therefore, proper management frameworks and investigations are needed to prevent and control influenza outbreaks and manage severe forms of the illness. Developing new antiviral drugs and vaccines with higher efficacy could also be a major improvement. We can also learn from the current COVID-19 pandemic and prepare ourselves for the possible influenza pandemics in the future. A better understanding of the animal-to-human transmission process could also prevent emergence at the source. We should not forget that influenza control in humans is not enough, and influenza control in animals should also be considered (Krammer et al., 2018; Santibañez et al., 2009).

Introduction

The Paramyxoviridae family belongs to the order Mononegavirales consists, it is one of the largest and fastest growing family causing significant disease burden in human and wildlife (Henrickson, 2003). The Paramyxoviridae family is divided into three genera: Paramyxovirus genera includes the Parainfluenza viruses and mumps virus, Pneumovirus genera includes RSV and Morbillivirus genera includes the measles virus (Baron, 1996). Measles virus, mumps virus, RSV and HPIV are best known because of the greatest burden of disease on humans. Moreover, other viruses of Paramyxoviridae family were also dangerous and have caused diseases in animals such as Canine Distemper virus that causes disease in dogs, Phocine Distemper virus that causes disease in seals, Cetacean Morbillivirus which causes disease in dolphins. . . . This chapter refers primarily to the virus in humans.

In the second to fourth centuries in China and the Roman Empire, scientists documented the first measles outbreaks (Brown, 1997). Measles is a highly contagious and serious disease that causes about 2.6 million deaths a year. Cyclical outbreaks of major epidemics around 2–3 years (as reported by WHO in 1968). Measles is an acute systemic disease, after cured it will create lifelong immunity for patients (Panum, 1939). Two epidemiological parameters of measles have been estimated, the reproductive number (R_0) and the critical community size (CCS). R_0 is defined as the number of secondary cases arising from each primary case and CCS is the minimum number of people needed for the disease to continue to exist. For measles, R_0 is about 15–20 cases and CCS is about 250,000–500,000 people (Bellini and Rota, 1998, Griffin, 2001).

Mumps is a virus of the genus Rubulavirus, which was first discovered through aerosol droplets by Hippocrates in the 5th century BCE. Mumps has a very narrow host range, which is similar to measles (Brown, 1997). Mumps epidemics can occur in both developed and developing countries, mainly caused by vaccination failures (Carbone and Wolinsky, 2001). These epidemics is also cyclical every year, it's estimated that between a few hundred and few thousand people in the United States getting mumps each year (as reported by CDC in 2018). Mumps has two indicators similar to measles, which are $R_0 = 5$ and $CCS = 200,000$ (Gower et al., 2005).

The RSV that causes in human is called human respiratory syncytial virus (HRSV). RSV causes respiratory infections, mucosal cells in the infected respiratory tract combine to form a syncytium. RSV was first discovered in 1956 on chimpanzees infected with respiratory illness by Morris, Blount and Savage, after which they named the virus CCA (Chimpanzee Coryza Agent) (Blount Jr. et al., 1956). It was later realized that the chimpanzees caught the infection from their caretakers. By 1957, Robert M. Chanock had determined that RSV causes pneumonia and laryngitis in children (Chanock et al., 1957). Today, RSV is the main cause of lower respiratory tract infections in infancy and childhood. According to statistics in the United States every year, with only infants, HRSV causes 50% of all pneumonia and 90% of bronchiolitis. 90,000 children in the United States each year hospitalized with RSV, one-third develop lower respiratory tract disease. In addition to children with mild illness, there are cases progressing to severe bronchiolitis and pneumonia, the lower submucosal edema and the bronchioles become blocked, in the worst case, mechanical ventilation may be required (Hall et al., 2009).

HPIV is a virus that causes parainfluenza in humans. It is the second reason that children under 5 years old hospitalized for respiratory disease, just behind HRSV. The nomenclature and classification of HPIV have changed a lot since the discovery of this virus. HPIV is documented in medical literature from the 1950s, however, it was not until 1959 that the virus was officially recognized and called "parainfluenza viruses" (Enders, 1996). HPIV is divided into four categories with names in the order of 1–4, including HPIV-1, HPIV-2, HPIV-3 and HPIV-4. HPIV-1, HPIV-2 and HPIV-3 are the main causes of diseases of the lower respiratory tract in infants, childhood, the elderly, and the immunocompromised (Henrickson, 2003). The results of the surveys show that about 75% of children over 5 years old have antibodies to HPIV-1 (Mizuta et al., 2012). In the United States, it is estimated that 5 million children have lower respiratory infections each year and a third of these cases are caused by HPIV-1, HPIV-1, HPIV-2 and HPIV-3 (Denny and Clyde Jr, 1986). Currently, the scientific literature on HPIV-4 is not popular and clear. In addition to lower respiratory tract infections, HIPV also causes upper respiratory tract infections however at a lower rate.

Biology of paramyxoviridae viruses

General biological characteristics of the Paramyxoviridae family is polymorphic structure, it consists of a helix nucleocapsid core, a lipid envelope and membrane binding proteins. They typically encode 6–10 proteins (5–250 kDa), of which all the viruses of the Paramyxoviridae family consist of three nucleocapsid binding proteins and three membrane-binding proteins. The retinol binding proteins (RBP) and fusion proteins are glycosylated by the N-linked carbohydrate side chain (Rima et al., 2019). The lipid envelope is derived from the plasma membrane of the host cell. In addition, the virions comprise about 6% carbohydrates by weight, composition of which is dependent on host cell. In terms of shape, virions with a spherical shape with a diameter of 100–400 nm are most common, however we can still see filamentous virions. The membrane of the virus of this family have two spines stuffing out 8–20 nm, these are the protein tetramer spines and the trimer or tetramer spines of fusion proteins (Morrison, 1998). About the genome, the axit ribonucleic (RNA) molecules inside the virions are straight, sensory-negative, no single infection but potentially infectious if the ribonucleoprotein (RNP) complex is introduced into the cytoplasm. For effective replication, the genomes of all viruses in the Paramyxoviridae family are required to be multiples of 6. Besides the common biological characteristics of the Paramyxoviridae family, each virus has different characteristics.

Measles virus is a negative, non-segmented, and lipid sheathed virus. The genome of the measles virus is about 16 kilobases long, and it consists of 6 genes that encode 8 proteins. Measles virus RNP complex is made up of nucleoprotein (N), phosphoprotein (P) and large protein (L) and is surrounded by this complex as matrix protein (M). In addition, this virus have two unstructured proteins (proteins V and C), they are expressed from an alternative RNA transcription of the P gene and are primarily effective in preventing interferon-induced immune responses (IFN) type 1. The glycoproteins, hemagglutinin (H) and fusion proteins in the measles virus envelope mediate virus attachment and fusion (Griffin and Oldstone, 2009, Bellini et al., 1985). After the measles virus converts into proteins and is encased in the lipid shell of the cell, it is sent out of the cell as a new virus. Within a few days of exiting a cell, the measles virus spreads through local tissue and is taken up by dendritic cells and alveolar macrophages, then be brought to the local lymph nodes. It continues to spread, eventually reaching the bloodstream, and spread mainly to many lung tissue and other organs such as the gut and brain (Moss and Griffin, 2012). After going to the organs of the body, measles virus reduces dendritic cell function of these organs, thereby causing immunosuppression due to measles (Rota et al., 2016).

The mumps virus contains a non-segmented negative, stranded RNA molecule, which contains 15,384 nucleotides (Davis et al., 2010, Hviid et al., 2008). The mumps genome contains seven parallel linked transcription units, including: nucleo (N), V/P/I, matrix (M), fusion (F) (Griffin), small hydrophobic (SH) (Jajosky et al.), hemagglutinin neuraminidase (Gower et al.) and large proteins (L). Each protein has different roles and functions. The RNP complex is the template for mumps virus replication and transcription, this complex is made up of negative-stranded RNA and surrounded by N protein. The RNA-dependent RNA polymerase is a complex of proteins L and P, it copies the negative sensory RNA to the positive and sensory RNA as a transcription enzyme that produces mRNA from the negative sensory RNP by entering a single promoter at the 3' end of the genome (Elango et al., 1988). When cells are infected, glycoproteins HN and F are transported through the endoplasmic reticulum and the Golgi complex to the cell surface. The M protein then locates RNPs to regions of the cell membrane, where glycoproteins F and HN have passed, thereby helping to infect a virus into a new cell (Li et al., 2009). The HN glycoprotein attaches the newly formed virus to neighboring cells via receptors such as sialic acid, which are abundant on the surface of most animal cells. The SH protein plays an important role in evading the host's antiviral response by blocking the TNF α -mediated path of death (He et al., 1998). Protein V is also involved in evading the host's antiviral response in the same way as the SH protein (Andrejeva et al., 2004). However, the function of protein I has not been clearly published.

The biological structure of the HRSV is spherical and is around 150 nm in diameter. There are fibrous species that have been observed up to several micrometers in length (Gower et al., 2005). Like other viruses, the RNA genome is encapsulated as a non-segmented and photoreceptor molecule. RSV has 10 genes and encodes 11 proteins (Lee et al., 2012). Proteins and functions of each include: internal structural proteins (matrix protein M and nucleoprotein N); proteins required for functional polymerase complexes (phosphoprotein P and polymerase L); non-structural proteins that evade the innate immune response (NS-1 and NS-2); trans membrane glycoproteins (small hydrophobic SH protein, glycoprotein G and F fusion protein) and M2 proteins that regulate transcription or transcription (the anti-inhibitory protein M2-1 and M2-2) (Tawar et al., 2009). About genome, it is approximately 15,000 nucleotides in length and is composed of a single strand of RNA with negative polarity. RSV is divided into two main strains of virus, RSV-A and RSV-B, which are both seasonal circulating in the human population. The RSV-B strain is found in the majority of the population and mainly causes disease without clinical symptoms. The RSV-A strain is known to be associated with most of the clinically important diseases and outbreaks. The HRSV genome was fully explored in 1997. To date, 10 genotypes of HRSV-A have been discovered including GA1 to GA7, SAA1, NA1 and NA2. The HRSV-B strain has 8 genotypes, including GB1 to GB4, SAB1 to SAB3 and BA1 to BA6 (Lee et al., 2012).

Scientists have proved that HPIV has a pleomorphic enveloped. Their envelopes are known to originate from host cells that have been infected with the last time. The size of HPIV is mostly about 150–250 nm, this is one of the medium sized viruses. However, scientists have also discovered much larger viruses (Howe et al., 1967). HPIV usually contains negative single-stranded RNA (in addition to mRNA), in addition, positive virions are said to be non-infectious. Like RSV, the HPIV genome contains about 15,000 nucleotides (Storey et al., 1984). The nucleotides are engineered to encode at least six common structural proteins, such as 3'-NPCMF-HN-L-5' (Tashiro and Homma, 1985). HPIV has different characteristics from other genera of the Paramyxoviridae family, for example that HPIV does not have neuraminidase like morbillivirus genera (measles virus ...), HPIV has thinner nucleocapsid than pneumoviruses genera (RSV, metapneumoviruses) (Henrickson, 2003).

Pathology of paramyxoviridae viruses

The viruses that belong to the Paramyxoviridae family have different pathologies. Instead of describing their general pathology of Paramyxoviridae family, we describe the four most typical viruses: Measles virus, Mumps virus, RSV and HPIV.

The first recognizable clinical sign of measles is usually a high fever, which starts 10–12 days after exposure to the measles virus and usually lasts 4–7 days. In addition, the early stages can also detect symptoms such as a runny nose, red and watery eyes, cough and small white spots inside the cheeks (CDC, 2018). After a few days, a rash called Koplik spots appears, usually on the face and upper neck (Biesbroeck and Sidbury, 2013). The rash spreads and eventually spreads to the hands and feet in about 3 days. After that, the rash lasts for 5–6 days and fades away. Most of us will emerge spots rash after exposure to the virus from 7 to 18 days, but the average of about 14 days (Steichen and Dautherville, 2009). Before disappearing, the rash is said to be “stained” and changes color from red to dark brown. Most measles usually cures after about 3 weeks from the date when symptoms are first discovered (Ludlow et al., 2015). After recovering from the disease, complications of measles ranging from mild to severe such as diarrhea, pneumonia, otitis media, laryngitis, corneal ulcers and acute encephalitis ... are relatively common (O’Brien, 1955, Fisher et al., 2015, Anlar, 2013, Semba and Bloem, 2004). Measles can be fatal, but fatalities are mostly associated with severe complications. Children under 5 years old or adults over 30 years old are at high risk of serious complications. Children with vitamin A deficiency, poor nutrition and people with weakened immune systems from HIV/AIDS or other illnesses are more likely to get measles. According to a 2018 WHO report, an estimated 140,000 people die from measles and the majority of them are children under 5 years old. Now, measles remains one of the highest causes of disease burden and mortality in children in the world (Griffin et al., 2012).

With mumps, the initial symptoms as an important signal include a low-grade fever, headache and feeling generally unwell. The most important symptom is swelling of one or both parotid glands, which will last for about a week. In addition, other symptoms of mumps include dry mouth, facial pain, ear pain, and difficulty speaking (Davis et al., 2010). When infected, the percentage of patients with parotitis is very high, ranging from 31% to 61%. This percentage depends on the age and immunity of each person, it can be as low as 9% or as high as 94% (as the report by CDC). Parotitis can appear in one or both ears, and it can also affect one or more salivary glands. Parotitis usually occurs within 2 days of exposure to the virus and the first symptoms are mostly ear pain and pain when touching the corner of the jaw. After 10 days these symptoms tended to decrease and after a week the symptoms usually resolve. The most common complication of mumps is testicular inflammation (orchitis), but it only occurs in men after puberty. This is a very dangerous complication, with a 15–20% chance of it occurring in men who have completed puberty and have mumps virus infection (Davis et al., 2010). Symptoms of orchitis are usually sudden swelling and pain in the testicles, nausea and vomiting, and fever. Pain and swelling symptoms usually subside after 1 week, but can last for several weeks depending on the case. In addition to orchitis, complications of mumps are usually quite severe and are also relatively common, including encephalitis, ovarian inflammation, deafness and acute pancreatitis (Senanayake, 2008, Di Pietrantonj et al., 2020).

RSV is one of the most common viruses that cause disease in humans, and it often returns, partly due to a lack of immunity long after infection. The incubation period of this disease is about 4–5 days (Bont et al., 2016). RSV usually affects the upper respiratory tract, but has the potential to also affect the lower respiratory tract, depending on the condition and severity of the disease. If the illness only affects the upper respiratory tract, it usually presents itself as flu-like symptoms such as nosebleeds, stuffy nose, cough, sneezing, sometimes fever and muscle aches. RSV may be related to the lower respiratory tract in some patients, especially those with risk factors for severe illness under 2 years of age. When affecting the lower respiratory tract, patients with symptoms similar to the symptoms of bronchiolitis, for example bad breath, rapid breathing, use of accessory muscles, wheezing. Severe complications such as viral pneumonia, hypoxia, acute otitis media, coma, asthma, apnea, and acute respiratory failure can also occur in people with RSV (Omer et al., 2019). Mild symptoms are more common in adults, they are very difficult to distinguish from a common cold because the symptoms are very similar as mentioned above. In the United States, according to CDC statistics has shown that RSV is the most common cause of bronchiolitis and pneumonia in children under 1 year. The rate of children under 2 years old suffering from this disease is up to 90% and the rate in older children and adults is also very high (Schweitzer and Justice, 2020).

Like RSV, HPIV are common respiratory pathogens caused by the community, however this disease occurs without ethnic, socio-economic, sex, age or geographic boundaries. However, scientists have also found a few factors that make HPIV easier to happen such as malnourished children, overcrowded housing, lack of vitamin A, lack of breastfeeding or environmental pollution (Berman, 1991, McIntosh, 1991). The HPIV-1 strain is cyclical and occurs in the fall for two consecutive years (Carballal et al., 2001). In the United States, among pneumonia cases, at least 50% of cases are caused by HPIV. Each outbreak of HPIV-1 in the United States involves 18,000 to 35,000 children under the age of 5 being hospitalized (Marx et al., 1997). HPIV causes infections such as bronchiolitis, tracheitis, pneumonia, fever, and wheezing. Most infections occur in children aged 7–36 months, but the incidence is highest in children aged 2–3 years. The HPIV-2 strain also causes infection every 2 years along with HPIV-1 or it can replace HPIV-1 in each outbreak (Belshe et al., 1983). HPIV-2 usually breaks out in the fall and early winter. The symptoms of this strain are similar to those of a lower respiratory tract infection. According to statistics, about 60% of all HPIV-2 infections occur in children under 5 years old and the highest incidence is from 1 to 2 years old. Particularly, infants under 6 months of age are very susceptible to infection with the HPIV-3 strain, in addition to those with immunodeficiency and chronic diseases. For the HPIV-3 strain, bronchitis and pneumonia are the most common infections. The HPIV-3 strain differs from the previous two strains, causing the annual spring and summer outbreaks. The region of this strain circulates mainly in North America and Europe (Belshe et al., 1983). The strain HPIV-4 has not been fully studied, it is thought to be a common disease, but it is usually mild and rarely detected (Henrickson, 2003). In addition to causing major infections of the respiratory tract, rare cases of HPIV have also been associated with viral meningitis.

Transmission of paramyxoviridae viruses

The paramyxoviridae family has horizontal transmission and the main route is air and direct contact. There are no documents to confirm that these viruses transmit via vectors. Viruses of this family enter the human body and usually start in the respiratory tract, they may not spread to other sites like the HPIV-1 virus and can spread to secondary sites such as lymphoid tissue and endothelium. For measles virus, parotid glands with mumps virus.... Host immunity is a critical condition for infection and reversibility caused by the paramyxovirus family of viruses. Long-term persistent infection can be caused by certain viruses of the genus morbillivirus, for example, the measles virus in subacute sclerosing encephalitis, a serious complication that affects the central system and has a moderate duration is 8 years (Enders, 1996). In addition to the general characteristics of the paramyxoviridae family, the differences in transmission of each virus will be highlighted below (mainly four viruses that cause disease in humans: Measles virus, Mumps virus, RSV and HPIV).

Measles is considered one of the most contagious diseases in the world, as a report by WHO. Measles is transmitted through the air, which is easily spread from person to person through the coughing and sneezing of an infected person. It can also be spread by direct contact with the mouth or nose secretions of an infected person. Measles is so contagious that 9 out of 10 people sharing the same living space with an infected person will become infected. Before and 4 days after the rash appears, the patient is capable of transmitting the measles virus to others, which is difficult to detect and prevent. Measles can easily erupt into an epidemic and cause enormous burden and mortality, especially in malnourished young children. Most measles are eliminated in countries today, but cases imported from other countries remain an important source of infection. Based on the biological properties, the high transmissibility of measles can be explained by three reasons (Laksono et al., 2016). First, measles patients must be effectively eliminated from the measles virus in order to fully recover from the disease and be unable to infect others. Second, the virus must remain infectious until it reaches a new host. Third, the infectious nature of the measles virus is strongly related to the infectious dose of the virus.

Mumps virus is transmitted with respiratory (Davis et al., 2010). When the patient is infected with the mumps virus, it multiplies in the nasopharynx and regional lymph nodes. The patient can then transmit the virus by coughing, sneezing or talking, sharing objects that may have saliva, or by direct or indirect contact with the patient's respiratory secretions. Because it can persist on surfaces and then spread after contact, the mumps virus is highly contagious (Kutty et al., 2010). The virus can spread to many organs of the body, including the meninges and glands such as the saliva, pancreas, testes and ovaries. The tissues of the infected organ will become infected, and characteristic signs of parotid gland inflammation and aseptic meningitis appear. The incubation period for the mumps virus is 12–25 days, but usually 16–18 days. In many cases, people infected with mumps virus do not show symptoms, this rate is about 20–40%, so people can become infected and spread the virus to healthy people without knowing it (Kutty et al., 2010). The mumps virus is quite contagious like flu and rubella, but less contagious than measles virus.

RSV transmission is also the respiratory tract. The incubation period of RSV can last from 2 to 8 days, but an average of 4–6 days. In particular, infants and people with weakened immune systems can continue spreading the virus even after symptoms have stopped, for up to 4 weeks (Schweitzer and Justice, 2020). According to the CDC, the virus spread appears when the sick person coughs or sneezes. Droplets from the cough or sneeze of an infected person shot in the eyes, nose and mouth of an uninfected person or an uninfected person touch surfaces or virus and then touch the face before washing their hands. RSV can be spread through direct contact with the virus by acting like kissing the face of someone with RSV. This virus can persist for half an hour or more on hand or up to 5 h on a table top. After RSV inoculation into the nasopharyngeal mucosa or conjunctiva mucosa, the virus quickly spreads into the respiratory tract and reaches the apical ciliated epithelial cells, which is the preferred growth medium for RSV. According to some studies, HRSV can be transmitted from human to ape and also can be transmitted from ape to human, however this is not common.

In addition, RSV has also been recovered from cattle, goats and sheep but they are not considered the main vectors for disease transmission.

HPIV transmission studies are not common. One study found that only 2 out of 40 children were infected at a distance of 60 cm from the strain HPIV-1 (McLean et al., 1967). Consequently, small particle aerosol transmission can occur. Transmission by close and indirect contact through an RSV surface occurs by misting large droplets. In particular, the surfaces containing RSV can be direct self-inoculation (Hall et al., 1981). Scientists have proven that strains HPIV-1, HPIV-2 and HPIV-3 can last up to 10 h on non-porous surfaces and 4 h on porous surfaces (Brady et al., 1990). However, HPIV-3 is believed to be less capable of living in the external environment. The experiment was conducted on two human fingers, when HPIV-3 was added to the first finger, more than 90% of the virus on that finger lost its ability to infect another finger in just 10 min (Ansari et al., 1991). It was also found from that experiment that person-to-person transmission by direct hand contact did not seem to be a means of transmission. However, the amount of virus excreted from an acutely infected child can be 10 times greater than when tested, so exact conclusions cannot be drawn (Hall et al., 1977). In outdoor environments, HPIV can be easily removed from surfaces with most common detergents or disinfectants (Brady et al., 1990).

Associated conditions of paramyxoviridae viruses

About Measles virus, it is also a locally circulating disease in urban communities and is an epidemic disease with a cycle of 2–3 years or longer depending on each country. Measles occurs seasonally. Measles occurs at different times if in different geographic areas.

Measles occurs at different times if in different geographic areas. In temperate climates, measles usually occurs in late winter and early spring. In the tropics, measles is more common in the dry season (Griffin et al., 2012). Risk factors for measles infection have been specifically studied, including immunodeficiency caused by HIV or AIDS (Gowda et al., 2012), immunosuppression after organ transplant or stem cell transplantation, alkylating agents (Waggoner et al., 2013). Additionally, vitamin A deficiency is an important factor associated with measles in children. A 2017 study showed that vitamin A supplementation significantly reduced mortality and morbidity in children with measles (Imdad et al., 2017). The recommended dose of vitamin A for all children with acute measles is 50,000 IU for infants <6 months, 100,000 IU for children 6 to 11 months, and 200,000 IU for children >12 months. Vitamin A should be taken by mouth once daily for 2 consecutive days with the above dose (Lindberg et al., 2015). In addition to vitamin A, zinc supplementation for children with measles is also mentioned, however, it has not been adequately studied for its effects and dosage. The factor that seems most important is the measles vaccine. Before the popular measles vaccine, over 90% of people before the age of 20 have contracted measles, very few people are not infected with measles. According to WHO statistics, about 100 million people get sick and 6 million people die from measles each year. However, after the dissemination of the measles vaccine, measles has seen very positive improvements, such as an 80% reduction in deaths between 2000 and 2017. By 2017, 85% of children worldwide received the first dose (as the report by WHO).

Mumps occurs worldwide. However, the incidence is higher in densely populated areas with low living standards, and in areas that are often cool or cold. Mumps also has an outbreak time depending on geographic location. It usually occurs year round in the equatorial region and winter and spring in the northern and southern regions of the world (Anon, 2007). The cool, cold, and dry climate allows mumps to spread more strongly. Mumps usually occurs in preschool children, or high school children, can also be found in older children or adolescents and the elderly at a lower rate (Di Pietrantonj et al., 2020). The incidence of mumps is significantly different between men and women, men often suffer more than women. The only known natural host of the mumps virus is humans. Mumps is spread through direct contact or through airborne droplets from the upper respiratory tract of an infected person. Mumps is less susceptible to comorbidities, but is spread mainly by close contact.

RSV is like measles and mumps virus, it varies from season to season but depends on geographic area around the world. The disease usually occurs in winter-spring in temperate climates and occurs in all seasons around the equator. The biggest risk factor for serious illness from RSV is age (Hall et al., 2009). Several epidemiological studies have also identified several factors that can increase the severity of RSV infection, specifically, tobacco smoke and cooking smoke, low socioeconomic status, associated medical conditions. . . (Chen et al., 2014, Wu et al., 2015). The patient's immunity and pathology can affect the patient including premature birth, low birth weight, immune disorders, genetic and chromosomal abnormalities such as Down syndrome and congenital heart defects (Cilla et al., 2006, Fixler, 1996).

HPIV lasts only a few hours and is easily destroyed by soap, detergents, disinfectants and even water. The pH, humidity and temperature of the environment are important factors affecting the survival of HPIV. A pH of 7.4–8.0 causes the infectiousness of HPIV to decrease. In addition, high temperatures above 37 °C and low humidity also reduce the possibility of virus infection (Hambling, 1964). Hospital infection is also one of the causes of the disease. Infection due to chronic medical care or surgery is one of the 'hot spots' of the health sector. In addition, other factors that have been studied that are associated with disease risk include malnutrition, vitamin A deficiency, not breastfeeding, environmental pollution, seasons and crowding (Henrickson, 2003).

Controls of paramyxoviridae viruses

Measles virus vaccine was discovered and widely used. This vaccine is formulated from wild species, then cultured under conditions that render them lethal without losing inherent immunity (Sood et al., 2017). Currently, an important public health strategy for reducing measles deaths is routine measles vaccination for children, combined with mass immunization campaigns, especially in countries with high morbidity and mortality rates. Currently, developed countries often use a combination vaccine for measles, mumps and rubella (MMR), known as the German measles vaccine. Children need their first shot at 12–15 months of age. Then, when the child is 4–6 years old, parents need to give their child a booster shot, or it can also be repeated any time 4 weeks after the first shot. In countries with relatively high rates of measles, the first shot is possible at 6 months of age (Bester, 2016). Common use of the measles vaccine has persisted for nearly 60 years. This vaccine has many advantages such as safety, effectiveness and cost. However, the measles vaccine is a live-attenuated one, so pregnant women, children with primary immunodeficiency, children with tuberculosis, cancer patients, transplant patients, patients used immunosuppressants or with advanced AIDS should not be used for treatment (World Health Organization, 2019). On the other hand, within 6 days of exposure the source of infection, use of globuline can prevent or reduce the severity of measles. This is expensive precautions and not popular. Even in developed countries, only a few cases are recommended to use this method, it is a pregnant woman who is not immune to measles and children were born to mothers do not have immunity against measles. . . So the simplest and most effective method is still vaccination according to the national program.

For mumps, the most common preventive measure is vaccination against mumps. This vaccine was developed by American microbiologist Maurice Hilleman (Buynak et al., 1969). The mumps vaccine can be given alone or as a combination of mumps, measles, rubella or mumps, measles, rubella and varicella (MMRV) vaccine (Di Pietrantonj et al., 2020). The use of the mumps vaccine is recommended by WHO in all countries with childhood immunization programs. In 2015, out of 194 WHO member countries, 121 countries (62%) included mumps vaccine in their national immunization programs, most of which used MMR vaccine. Since then, good results have been achieved in reducing the morbidity burden caused by mumps, for example the incidence

of the disease has decreased significantly in countries where large-scale immunization has been introduced. The most obvious example is in the United States, since the mumps vaccine was widely used in December 1967, the incidence of mumps has steadily declined, falling from 1,51,209 cases in 1968 to 265 cases per year from 2001 to 2008 (Jajosky et al., 2006). In addition to the vaccine, mumps also has therapeutic measures, but it is only supportive. Treatments for symptom relief include applying ice or hot compresses to the affected neck or testicles and using acetaminophen to relieve pain (Davis et al., 2010). A very important measure to prevent mumps is quarantine. Mumps is most contagious 5 days after symptoms first appear, should be quarantined in this time. Standard precautions are needed for hospitalized patients. Medical staff with mumps should be absent for 5 days (Kutty et al., 2010).

As mentioned above, worldwide there are 33 million lower respiratory cases and up to 199,000 child deaths caused by RSV. The burden of disease has made the development of the RSV vaccine a priority for over 50 years. However, there is currently no vaccine available for any of the age groups where RSV normally causes illness including infants under 6 months old, babies 6 months to 24 months old, pregnant women and the elderly (Schmidt and Varga, 2017). There is now a drug to help prevent the serious RSV disease called Palivizumab. This medication is often used for premature infants, congenital heart disease, or chronic lung disease. Palivizumab can help prevent RSV from getting worse, but it cannot cure or treat children who already have RSV, nor can they prevent RSV infection (Andabaka et al., 2013). From there, proactively preventing the spread of RSV is the most important and effective measure. As recommended by the CDC, if you have cold-like symptoms or suspected RSV, don't cover coughs and sneezes with your hands, and instead use a tissue or the upper sleeve of a shirt. In addition, it is advisable to wash your hands frequently with soap for 20 s, avoid direct contact or shake hands and share personal equipment with a suspected person.

Like RSV, HPIV also has no specific vaccine that has been found. The trials found the vaccine strains of HPIV specificity-1, HPIV-2 and HPIV-3 were conducted (Sato and Wright, 2008). There was a trial that used recombinant technology to create vaccines for three strains of HPIV-1, 2 and 3, which resulted in a number of live vaccines attenuated. These vaccines have been shown to have good immunity and resistance to HPIV-3 in phase I trials. However, for strains HPIV-1 and HPIV-2, the result was worse (Durbin and Karron, 2003). However, these vaccines are quite limited and are not an effective one. In addition to vaccines, maternal antibodies may provide some degree of protection against HPIV through colostrum in breast milk in early childhood. The use of drugs to treat HPIV has also been found. There is a drug called Ribavirin, which is a broad spectrum antiviral and is currently being used by people with severe immunodeficiency, but its benefits are not really clear. If a secondary infection occurs, antibiotics may also be used. Antibiotics commonly used are corticosteroids, along with a nebulizer to treat lung cancer if breathing problems occur (Sato and Wright, 2008).

Glossary

Carcinogenesis Cancer inducing factors is a multistage phenomenon involving modification of genes by mutagenesis that important in regulation of normal cellular function and cause cell transformation.

Cervical cancer A sexually transmitted viral cancer that occurs in the cells of the cervix with several types of the human papillomavirus.

Papillomaviruses A group of DNA viruses that cause the formation of papillomas or warts.

Persistent infection Persistent infections are characterized as those in which the virus is not cleared in acute phase of infection and last for long periods in the specific cells of infected individuals.

Species-specific A substance or organism that is limited to or found only in one particular species.

Viral clearance A function of the innate immune system, consistent with the rapid kinetics of virus elimination and defined for removal of virus contamination or refers to the time it takes for a virus to no longer be detected in samples or in side tissues.

Virus-like particles (VLPs) The molecules that contain multiprotein structures are closely similar to viruses but are non-infectious.

History

The timeline of virus emergence and evolution have been inspected using ancient DNA, in which evolutionary analysis is performed based on DNA viruses derived from archival materials. This approach has been more successful in the case of human wart-causing papillomaviruses (PVs) as the important examples of ancient DNA virus. Their infectious viral nature was recognized in the early 1900s. Subsequently, PVs were identified in a variety of vertebrate species in addition to humans. The PVs are species-specific in their host ranges, the biology of human PVs must be investigated in their natural host. The first animal PV was identified in the 1930s by Richard Shope. The Shope papillomavirus, now designated the cottontail rabbit papillomavirus (CRPV), that was the first identified DNA tumor virus. Some of the human papillomaviruses causing benign papillomas, but the others undergo to malignant progression. The molecular cloning of PVs in the 1970s, significantly enhanced the ability to study their biological characteristics and biochemical properties. The bovine papillomavirus type 1 (BPV1) represented as a prototype virus in *Papillomaviridae* because the virus induced focal transformation in rodent cell lines (Black et al., 1963). The molecular cloning and sequencing of the cloned PV genomes led to the identification of open reading frames (ORFs) as putative viral genes of the human *papillomaviruses* (HPV) and recognized that they have multiple HPV genotypes, and some types was closely associated with human cancers, including cervical cancer (Fields et al., 2013; Furumoto and Irahara, 2002).

The typical members of *Papillomaviruses* had particular unique characteristics including:

- I. Papillomaviruses are small, non-enveloped, icosahedral DNA viruses and their size, which at 52–55 nm and composed of 72 pentamers.
- II. The genome consists of circular double-stranded DNA (C-dsDNA) molecule of about 8000 base-pairs (bp) that is bound to cellular histones.
- III. The genomes have an average GC content of about 42% (36–59%).
- IV. The nucleus is the site of viral replication and virion assembly.
- V. Papillomaviruses are highly species-specific, tissue-restricted, and do not infect other species even under laboratory conditions; therefore, humans are the only known reservoir for HPVs.
- VI. Papillomaviruses have been characterized by molecular methods.
- VII. About 90% of HPV infections cause no symptoms and resolve spontaneously within 2 years (Ljubojevic and Skerlev, 2014).
- VIII. HPVs cause mucosal and cutaneous lesions in humans, and in some cases, HPV infection persists for years and results in either warts or precancerous lesions.
- IX. Translation of early and late transcripts, alternative splicing, alternative open reading frames.

Classification of papillomaviruses

Taxonomy

Classification of the *Papillomaviridae* is based on sequence identity across the L1 open reading frame (Van Doorslaer et al., 2018; De Villiers et al., 2004). The virus taxonomy (2019 Release) revealed the *Monodnaviria*, *Shotokuvirae*, *Cossaviricota*, *Papovaviricetes*, *Zurhausenvirales*, *Papillomaviridae*, *Firstpapillomavirinae*, *Alphapapillomavirus*: *Alphapapillomavirus* 1–11, 13 and 14. The *Betapapillomavirus* containing *Betapapillomavirus* 1–4, *Gammapapillomavirus* containing *Gammapapillomavirus* 1–5, *Mupapillomavirus* containing *Mupapillomavirus* 1–2 and finally *Nupapillomavirus* containing *Nupapillomavirus* 1 up to final released data (Krupovic and Koonin, 2017). The family includes two subfamilies, *Firstpapillomavirinae*, which includes 53 genera, 133 species, and *Secondpapillomavirinae*, with a single genus and species. This chapter focuses on the human *papillomaviruses* whose member genres include *Alphapapillomavirus*, *Betapapillomavirus*, *Gammapapillomavirus*, and *Deltapapillomavirus*. Genera are named according to the Greek alphabet. The high-risk human papillomaviruses (HR-HPV) which known as HPV 16 and 18, cause more than 99% of cervical carcinomas belong to the subset of mucosotropic HPVs alpha genus (Walboomers et al., 1995). A subset of cutaneous HPV types classified into the beta genus (*Betapapillomaviruses*), called epidermodysplasia verruciformis (EV) which, are consistently found in non-melanoma skin cancers (De Villiers, 1998). These skin lesions mainly arise at sites of the body that are exposed to the sun or during infection with human papillomaviruses (De Villiers et al., 2004).

The Papillomaviruses important genera, are classified based on ICTV2019 release are shown in Table 1.

Virion structure and family characteristics of HPVs

The papillomaviruses comprise a group of small, nonenveloped epitheliotropic icosahedral DNA viruses, that replicate in the nucleus of squamous epithelial cells. The papillomaviruses induce benign lesions of the skin (warts) and mucous membranes (condylomas). Some PVs have been implicated in the development of epithelial malignancies, especially cancer of the uterine cervix, other urogenital tract, and upper airway cancers (Fields et al., 2013).

The epidemiological data determined the more frequent association of specific species at HR-HPV types. Moreover, molecular cloning of the HPV genomes showed multiple HPV genotypes, that high risk types are closely associated with human cancers. PVs are classified principally according to the host species and have been traditionally referred to as types based on their DNA sequence. The PV genomes have been organized phylogenetically on the base of their DNA sequence, according to the relative homology of

Table 1 Papillomavirus classification based on ICTV2019 by focusing on important HPVs.

Family Papillomaviridae		Biological properties
Subfamily	Genus	
First papillomavirinae	53	
Second papillomavirinae	1	
Alpha-papillomavirus		Cause Mucosal and cutaneous lesions in humans with High and low-risk classification based on molecular biological data, immortalize human keratinocytes
Beta-papillomavirus		Cause cutaneous lesions in humans, infections exist in latent form in general population, activated under conditions of immune suppression. Also referred to as EV-HPV types due to close association with EV
Gamma-papillomavirus		Cutaneous lesions in humans, Histologically distinguishable by intracytoplasmic inclusion bodies specific for type species
Mu-papillomavirus		Cutaneous lesions in humans, Histologically distinguishable by intracytoplasmic inclusion bodies specific for type species
Nu-papillomavirus		Human papillomavirus Benign and malignant cutaneous lesions

the L1 ORF (Bernard et al., 2010). All PVs have a similar genetic organization comparable to the L1 DNA sequence between the most divergent genomes. Instead, two very closely related isolates may differ by only a single nucleotide (Bernard et al., 2010). A distinct type is share at least 10% nucleotide sequence different of other HPV types. HPVs are clustered to high-risk and low-risk HPV types based on molecular biological data including high-risk types for pre-cancerous and malignant lesions, and low-risk types containing benign lesions. Low-risk HPV types include types 6, 11, 42, 43, and 44. High-risk HPV types include types 16, 18, 31, 33, 34, 35, 39, 45, 51, 52, 56, 58, 59, 66, 68, and 70 (Ahmed et al., 2015).

HPV genome and ORFs

The PV particles are around 60 nm in diameter and consist of a single molecule of double-stranded circular DNA about 8000 base pairs (bp). The genomes of all HPV types contain approximately eight ORFs and all of them are located on one strand of the viral DNA. The ORF can be divided into three functional parts: the early (E) region encodes proteins (E1–E7) that are transcribed from the early promoter and essential for viral replication; the late (L) region encodes the structural proteins (L1–L2) that are transcribed principally from the late promoter and required for virion assembly; and a largely non-coding part which known as the long control region (LCR), contains cis-acting elements that are essential for the replication and transcription of viral DNA (Fig. 1). The viral LCRs contain constitutive enhancer elements that play an important role in the initial expression of the viral genes after virus infection and may also be important in the maintenance of viral latency. The E1 and E2 proteins of HPV act as factors that recognize the origin of replication. E4, is involved in the late stages of the life cycle of the virus and E5 may function during both early and late phases. The E6 and E7 proteins trigger a number of suppressor regulatory proteins of the cell cycle, primarily p53 and p105-Rb, respectively. Although, during the viral life cycle, E6 and E7 enable stable maintenance of viral episomes and induced cells differentiating to entering the S phase. The viral late functions, such as vegetative viral DNA synthesis, L1 and L2 late capsid protein synthesis, and virion assembly, occur exclusively in differentiated keratinocytes. Virion assembly and release takes place in the nuclei of terminally differentiated keratinocytes in which vegetative viral genome replication and expression of the virion proteins has occurred (Fehrmann and Laimins, 2003).

Life cycle and replication pattern of HPVs

The entry of HPVs to keratinocyte stem cells occurs through small wounds or close contact in the skin or mucosal surface. The virion transports to endosomes, the minor capsid protein L2 disrupts the endosomal membranes through a cationic cell-penetrating peptide and finally lead the viral genome to escape and enter to the cell nucleus, along with L2 (Zhang et al., 2018). After successful infection of a keratinocyte, the virus expresses E1 and E2 proteins, which are necessary for replicating and maintaining the viral DNA as a circular episomes. Papillomaviruses are extremely epitheliotropic and able to establish productive infections inside the skin or mucosal epithelia. The viral life cycle is related to the differentiation steps of the infected epithelial cells. As indicated, life cycle is initiated by the infection of basal epithelial cells, probably at the sites of injury by several potential receptors, that have been reported. After entry to the basal cells, the viral genome is transported to the nucleus, where it undergoes a limited amplification to a low copy number, and early genes are expressed preferentially at low levels. The early steps in the virus replication cycle, such as attachment, uptake, endocytosis, transport to the nucleus, and producing uncoated viral DNA, occurred as an early limited event. The early gene transcription is followed by translation of the E proteins and steady state viral DNA replication. The late events in the viral life cycle that lead to the production of virion particles occur in the differentiated keratinocyte, including vegetative viral DNA replication, transcription of the L region, and production of the capsid proteins L1 and L2. Assembly of the virion particles and release of viruses occurred in the nucleus. In the second stage of replication, these genomes are maintained as a stable multicopy plasmid at a constant copy number in the mitotically active basal cells (McBride, 2008; Fields et al., 2013). The ability of HPVs to establish their genome in basal cells depend on the E1, E2, E6 (Hubert and Laimins, 2002), and E7 genes expression (Flores et al., 2000). Generally, during basal cell division, the daughter cell migrates into the suprabasal compartment and initiates terminal

Fig. 1 Schematic representation of the HPV genome organization. The diagram illustrating the position of papillomavirus genes within the genome and their functions. Early regions involved in replication and transcription and late regions participate in viral structural proteins production.

differentiation. In HPV positive human keratinocytes and cervical epithelial cells, the suprabasal cells continue to support DNA synthesis and cell proliferation through HPV 16 E7 protein (Flores et al., 2000). Replication rates of papillomaviruses designated low and occurs concomitantly with the division of host epithelial cells. DNA viruses often replicate more rapidly than do their hosts. The HPVs activate the DNA replication machinery, by overexpression of E6 and E7 proteins to support vegetative viral DNA synthesis for packaging of progeny virions (Flores et al., 2000). This pattern of progeny production seems to be due to a tendency to establish persistent infections.

Pathogenesis

Human papillomavirus causes a wide range of tumors, from benign papilloma lesions (HPV types 6 and 11) to invasive squamous cell carcinoma (HPV types 16 and 18). All papilloma-based lesions can be benign or malignant, such as laryngeal and anogenital papillomas, which are clinically similar to other superficial squamous or invasive cervical squamous lesions (Burd, 2003). There is nowadays sufficient evidence that certain, so-called “high-risk” types of HPV are carcinogenic to humans in the cervix (HPV16, 18, 31, 33, 35, 39, 45, 51, 52, 56, 58, 59, and 66). In developing countries, carcinoma of the cervix uteri is the most frequent type of female (Farahmand et al., 2021).

HPV DNA can be found practically in all patients with cervical cancers, head and neck cancers, recurrent respiratory papillomatosis (laryngeal papillomatosis). The most predominant type in epidermoid carcinomas is HPV16 (Omland et al., 2014; Fields et al., 2013). HPV DNA was demonstrated in more than 50% of the less-prevalent carcinomas of the vulva and penis, and HPV16 is again the most frequent type, followed by HPV18. HPV infection is adequate to induce cancer cells in combination with other spontaneous or virus-induced modifications (Zur Hausen, 1991). The viral genes E6 and E7 are required to trigger these effects. They encode proteins that inactivate tumor suppressors and modulate cell-cycle regulation, DNA repair, and apoptotic processes by interacting with the cellular suppressor proteins of p53, p105-RB, p21, p27, Bak, and PDZ domain proteins. E6 activates the catalytic subunit of the telomerase as an important step in cell immortalization. E6 and E7 induce chromosomal instability, mitotic defects, which will contribute to tumor progression. The E6 and E7 proteins of high-risk viruses display much higher affinities to the cellular proteins than low-risks. High risk HPV DNAs appears integrated into the cellular genome in almost all HPV based cancers, which is a hallmark of cervical cancers.

Persistence and latency in HPVs

Persistence infection (long-duration of detectable HPV infection) is infrequent compared with clearance of infection, but the longer duration of infection with high-risk types of HPV may have implications for the pathogenesis of cervical intraepithelial neoplasia 3 (CIN3) and cancer (Moscicki et al., 2012). Latency for HPV infection has been described in animal models and recently, reactivation of latent infection has been demonstrated among immuno-compromised individuals (Maglennon et al., 2014).

Important oncogenic proteins of HPVs

E5 protein of HPVs

HR-HPV E5 is considered to be tumorigenic protein, because it transforms murine fibroblasts and keratinocytes in tissue culture systems. The E5 protein enhances the immortalization potential of E6 and E7 and, in association with E7, stimulates the proliferation of human cells. The major biochemical activities of HPV 16 E5 have been recognized in vitro by the ability of protein to enhance the activity of the epidermal growth factor receptor (EGFR) in the presence of ligand (Straight et al., 1993; Zhang et al., 2005).

E6 protein of HPVs

The E6 protein of HPV targeted p53 and association of E6 with p53 leads to degradation of p53 via recruitment of a ubiquitin ligase E6-AP. This interaction leads the inhibition of the transcriptional regulatory activities of the p53 protein in tissue culture cells (Li et al., 2019). The transforming gene products of papillomaviruses E6, required for efficient immortalization of primary human fibroblasts as well. Moreover, E7 cooperates with E6 to transform primary rodent cells and also requires for efficient immortalization of primary human fibroblasts or keratinocytes.

E7 protein of HPVs

HR-HPV E7 proteins are best known for their ability to associate with the cellular tumor suppressor protein of pRb (Gage et al., 1990). Association of HR E7 with pRb induced the degradation of pRb, through a proteasome-mediated pathway and disrupts the capacity of pRb to bind and inactivate cellular E2F transcription factors (Gonzalez et al., 2001; Fields et al., 2013). Correspondingly, several researchers showed that HR E7 combines with cyclin A/CDK2 complexes and inactivates p21 and p27. Therefore, E7 can interact with or alter numerous cellular factors that are involved in cell cycle regulation (Berezutskaya and Bagchi, 1997).

Other early and late proteins of HPV

Viral proteins E1 and E2 are assisting in the establishment of 20 to 100 episomal copies per basal cell and responsible for the maintenance of a low copy number of HPV genome. E2 is a DNA-binding protein that recruits E1 to the origin of replication, but also serves to regulate transcription of E6 and E7 from the early promoter. By expressing the early viral genes (E1, E2, E6, and E7), genomes of viruses replicate during host cell replication. The HPV genome migrates from the basal layer and in differentiated cells, production of E4 protein induces viral genome replication. Products of late genes L1 and L2 are needed to form new virions, which reach the cornified layer of the epithelium and are released after assembly (Fields et al., 2013). The main roles of individual produced proteins during the HPV cell cycle described in Table 2.

Incidence, persistence and clearance

Several published studies provide data on incidence of HPV infection and duration of clearance or latent infections. Approximately 5–15% of HPV-negative women are infected each year with one of the high-risk types of HPV. Moreover, the incidence of infection with high-risk HPV types rises to be higher than low-risk types (Muñoz et al., 2004). The most common types of infection occurred

Table 2 Human papillomavirus proteins and their functions.

<i>Protein</i>	<i>Function</i>	<i>Most important biological properties of HPV proteins</i>	<i>Associated cellular/viral proteins</i>
E1	Acts as adenosine triphosphatase (ATPase) and DNA helicase; necessary for replication of viral DNA	Transcription factor & helicase activity, Mediate episomal DNA replication	binding to specific origins of replication of viral DNA
E2	Main regulator of viral gene transcription; DNA replication and viral genomes segregation	Transcription factor & Regulate viral copy number, Regulate early gene promoters	The interaction of E2 with E1/
E3	Not known	Exists only in a few papillomavirus types with unknown function	–
E4	Acts late in the viral life cycle; favors viral genome amplification, regulates virus maturation	Facilitates virion release by destabilizing cyokeratin networks in epithelial cells	E1 E4 arrest cell cycle in the G ₂ phase
E5	Enhances E6 and E7 transforming activity, promotes chromosomal instability	Stimulate cell proliferation & Prevent differentiation, Down regulates surface MHC class I expression. Stimulate mitogenic signals of growth factors	E5 regulates growth signaling pathways & activates EGFR and the downstream Ras-Raf-MAP kinase pathway
E6	Disrupts normal regulation of host cell cycle via p53 degradation in the presence of E6AP, inhibits apoptosis, and activates telomerase	Viral major oncoprotein, Immortalization, Genomic instability, DNA damage responses, Cell proliferation and differentiation in suprabasal DNA synthesis, Induced malignant transformation together with E7	Interact with p53 & reduce p53 degradation potential, Bak, Myc, FADD/ Caspase 8
E7	Degrades tumor-suppressor protein pRb, affects the expression of S phase genes by interaction with transcription factors and histone deacetylases	Immortalization, Genomic instability, DNA damage responses, Cell proliferation and differentiation in suprabasal DNA synthesis, Induced malignant transformation alone or together with E6	E7 with their multiple cellular targets such as pRb and related super family
E8	Not known	The E8 genes are chemically and functionally similar to the E5 genes from some HPVs, and are also called E5/E8	–
L1	Major viral structural protein required for attachment to cell surface receptor	Major capsid protein & is the major component of the HPV prophylactic vaccine	The L1 protein has DNA binding activity and receptor binding protein, Containing nuclear localization signal (NLS)
L2	Minor viral structural protein; interacts with DNA. Contributes to viral localization into the nucleus and helps the packaging of viral DNA into capsids	Minor capsid protein & is an attractive candidate for cross-protective vaccines & disrupts the membrane of the endosome through a cationic cell-penetrating peptide	L2 escorts the genomic DNA into the nucleus, Cellular surface protein binding with L2 affect the cell tropism of mucosal HPVs.

by HPV 16, 18, 31, 33, and 51 among younger women respectively (Harper et al., 2004). Most HPV infections are transient and become undetectable within 1–2 years. On the other hand, the persistence of HPV infection is crucial for the development of cervical lesions and cancer. Undoubtedly, it seems that HPV infections are self-limited and cleared completely by the cell-mediated immune system or are suppressed into long-term latency (Fields et al., 2013).

Integration of HPV sequences

The papillomavirus DNA genome is frequently found integrated into the host chromosome. Integration of HPV genomes affects both viral and host gene expression. Integration of HPV can be found in premalignant lesions, particularly in grade 2/3 cervical intraepithelial neoplasia (CIN2/3). Cervical epithelial cells that anchorage integrated HR-HPV DNA have a selective growth advantage over cells that contain extrachromosomal viral genomes. It is the result of overexpression of E6 and E7 viral genes and continuous expression of these proteins can lead to the accumulation of mutations in the cellular genome (Harper et al., 2004; Fields et al., 2013).

Chromosomal abnormalities in HPV-associated cancers

Several chromosomal changes have been described in HPV-associated cancers. Aneuploidy, loss of heterozygosity are the most frequent events which associated with progression from high-grade lesions to cervical cancer (Nishimura et al., 2000).

Alterations of specific proto-oncogenes

Several studies have addressed the structural or functional alteration of different proto-oncogenes during HPV infection. Most of these alterations were evocative in nature and few were designed to correlate with progression of disease. A straight role for these genetic alterations in HPV-associated carcinogenesis is difficult to establish, but the RAS mutations in the RAS family of oncogenes have been described in premalignant and malignant cervical carcinomas (Mammas et al., 2004).

The c-MYC and HER-2/NEU amplification during HPVs infection

HPVs have been shown to integrate in the proximity of c-MYC, which altered HPV-associated lesions production. Abba et al. (2004) described c-MYC amplification in a high proportion of cervical cancers compared with benign and premalignant cervical lesions. Moreover, a significant association between c-MYC amplification and HPV 16 infection was observed. Although, HER-2/NEU mRNA and protein were detected in a large proportion of cervical adenocarcinomas. Preferential expression of this proto-oncogene was more strongly associated with lesions that contained HPV 16 (Abba et al., 2004).

Epigenetic events

Epigenetic events that involved the methylation of viral genes or LCR of HR-HPVs have been described. The LCR of HPV 16 and 18 (Badal et al., 2004) are hypermethylated in normal and low-grade cervical smears than high-grade smears. This incident correlates with increased transcriptional activity of the early region and consequently greater availability of the E6 and E7 proteins. Hypermethylation of cellular gene promoters has also been observed in cervical carcinomas (Zafari et al., 2018; Dong et al., 2001).

Methods for the detection of HPV infection

Microscopic abnormalities

Microscopic abnormalities are diagnosed in only a minority of women who have detectable HPV by DNA assays. Microscopic diagnoses are disposed to subjectivity and lack of interobserver reproducibility, particularly when mild or confusing changes are involved. The persistence of at least one carcinogenic HPV type is the necessary state for the emergence of precancer. However, other aspects of infection may contribute to the likelihood that an infection will progress, such as type of virus, viral load, and concurrent abnormalities. Among the oncogenic HPV types, HPV 16 is exclusively associated with considerable risk for cancer. Low viral loads, which detectable only by PCR, are associated with normal microscopic view. The value of increasing viral loads with respect to subsequent prediction of lesions, has not been established obviously (Lorincz et al., 2002).

Progression to precancer

The first critical difficult task is to define “precancer” lesion from precancerous ones, on the basis of histology. There is substantial heterogeneity in the microscopic diagnosis and biological meaning of CIN2 lesions in particular. Some acute HPV infections are poorly diagnosed by microscopic examination, while others are preliminary precursors that are supposed to continue at high risk of attack. Some non-carcinogenic HPV infections can cause lesions known as CIN2, indicating that this level of abnormal microscopic appearance is not a sufficient risk factor for cancer. CIN3 should be used as a surrogate for precancer and CIN2 as a buffer zone of ambiguous diagnosis. The attention should be restricted to women with carcinogenic types of HPV. The interval period between the onset of HPV infection and the incidence of precancerous lesions is about 7–10 years in young people. In general, cervical malformations persist longer and are more likely to progress in women with carcinogenic HPV infection than in women with non-carcinogenic infections or no HPV (Schlecht et al., 2003).

The cytology diagnostic methods cannot provide reliable estimates of the extent of the lesion. Because the vast majority of infection in CIN2 grades are transient and regress normally in short time, but some may lead to CIN3 or cancer. The average age of women with invasive cancers are more likely to be frequent in older ages. In several studies, it revealed that HPV DNA integration is associated with invasion. However, it is difficult to demonstrate that it could be causative factor.

Serology test

The effect of serum antibodies to HPV serotypes 6, 11, 16, 18 to risks of subsequent genital HPV infections investigated in several studies. Serology of viral like particles (VLPs) by ELISA methods is a very useful epidemiological tool for defining previous and current exposure to HPV infection. The assays are reasonably type-specific and are usually negative in individuals who have never been infected (Kjaer et al., 2001). The produced antibodies following natural HPV infection are not sufficient to protect against subsequent infection among women, but it is the markers of previous infections; although, some studies showed that antibodies provide partial immunity against subsequent infections and precancerous lesions. Differences in study findings may be due to the use of different antibody assays, serum antibody levels, and time since first exposure to HPV (Wilson et al., 2014).

HPV DNA detection methods

Assessment of previous infections is challenging, especially among individual have been sexually active for a long period of time. Furthermore, current conventional HPV DNA detection methods may not be sensitive enough to detect low viral load of latent infection or reactivations that last for a short time period (Pamnani et al., 2018; Farahmand et al., 2021).

Distribution of the most common types of HPV in women with and without cervical cancer

In some areas, the HR-HPV 16 and 18 positive DNA in cervical cancer is estimated more than 70% (Clifford et al., 2003). The most important types which appear after HPV16 and 18 are HPV45 and other HR-HPVs. There is a possibility of HR-HPV coinfection with two or more HPV genotypes as well, which can lead to cancer (Zeng et al., 2016). The highest incidence of cervical cancer was shown in women aged more than 60 years old in most areas, that the HPV vaccination is currently not a part of the national immunization program (Farahmand et al., 2021).

Innate immune responses against papillomavirus infection

HPV can gain access to the skin through the compromised integrity layers. In fact, epidermidis as an external surface is the first line of defense to protect humans in viral infection warfare and composed of basal germinal, granular, and keratinized layers (Flint et al., 2020).

Keratinocytes act as a non-professional antigen-presenting cell (APC) and participate as a part of the innate immune system to present antigen and provoke type 1T helper (T_{H1}) and type 2T helper (T_{H2}) cells expression through $CD4^+$ and $CD8^+$, respectively. Indeed, keratinocytes play as a cross link cell to improve the adaptive immune response (Nestle et al., 2009; Amador-Molina et al., 2013). Both keratinocytes and innate immune cells are nonprofessional cells that express pattern recognition receptors (PRR) which skilled to recognize pathogens thus named pathogen-associated molecular patterns (PAMPs) and also identify damage signals which known as damage-associated molecular patterns (DAMPs) (Nunes et al., 2018; Barros et al., 2018).

In this regard, the toll-like receptor (TLR) family may locate through expression on the cell surface or in endosomes. TLR 9 is an endosomal immunological receptor which able to recognize unmethylated CpG double-stranded DNA viruses such as HPV. TLR 9 can promote cell signaling to produce cytokines and type I interferon (IFN-I). It reveals that TLR 9 may perform as a key factor in viral clearance during HPV infection (Barros et al., 2018; Zhou et al., 2019; Hibma, 2012). There are some evidence that TLR 9 activation in keratinocytes lead to the production of tumor necrosis factor (TNF)- α , IL-8, CCL2, CCL20, and CXCL9 in addition to IFN-I (Lebre et al., 2007; Miller and Modlin, 2007). TLRs engagement with their ligands leads to activate the nuclear factor κ B (NF κ B) through transducing Toll/IL-1 receptor (TIR) signals into the cells and culminate this transcription factor to regulate inflammatory chemokines and cytokines (Barros et al., 2018; Delves et al., 2017).

Papillomavirus regulate the IFN amplification pathway and innate immunity

Type I interferon which known as antiviral interferon is the part of the innate immune system. They have also immunomodulatory and proliferative properties (Murphy and Weaver, 2016). IFN-1 secretion was climaxed within PRRs signaling transmission and followed by downstream IFN-regulatory factors (IRFs) pathways, the Janus kinase/signal transducers and activators of JAK-STAT transcription factors. Then, the NF- κ B signaling pathway restricts establishment of infection (Fensterl et al., 2015; Schneider et al., 2014). TLR 9, TLR 4, and IFN-inducible protein 16 (IFI16) PRRs can perceive the genome of HPV following initial infection and lead to IFN-1 expression (Cigno et al., 2015; Bahramabadi et al., 2019; Ferreira et al., 2020). Interferons are obviously important factors in innate immunity system to inhibit viral infection and obstruct tumoral effects. Moreover, they have an immune regulatory activity to protect cells around the disturbed region (DeCarlo et al., 2012). Signaling of TLR 9 leads to induction of type 1 IFN or inflammatory cytokines through myeloid differentiation primary response protein (MyD88), MyD88-IRF7 and MyD88-NF- κ B, respectively. MyD88 accomplishes as an adaptor and several TLRs require it to distribute their signals. MyD88 forms mentioned complexes and IRF7 phosphorylated by IL-1 receptor-associated kinase1 (IRAK1), IL-1 receptor-associated kinase4 (IRAK4), or I κ B kinase α (IKK α) and then displaced to the nucleus and result the activation of the type 1 IFNs gene expression (Fig. 2) (Barros et al., 2018; Kawasaki and Kawai, 2014; Zhou et al., 2013).

Different findings indicated that various types of human papillomaviruses which known as “high risk” such as HPV16 and HPV18 and “low risk” such as HPV6 and HPV11, make effects on down-regulation or up-regulation of TLR9 pathway by viral oncoproteins. (Fields et al., 2013; Yeo-Teh et al., 2018). HPV16 E6 and E7 oncoproteins play an important role to interfere with the innate immune response. Indeed, E6 and E7 are able to down-regulate TLR9 and lead to impaired activation of the immune system. It is notable that HPV16 is more significantly capable to promote down-regulation of TLR9 in comparison with HPV18 (Yeo-Teh et al., 2018; Hasan et al., 2007).

In keratinocytes, high risk HPVs augment the expression of IFN related developmental regulator 1 (IFRD1) and reduce RelA subunit at lysine 310 (K310) which cause acetylation of NF- κ B. Subsequently, acetylated NF- κ B lead to down-regulation of proinflammatory downstream cytokines such as IFN- α (Tummers et al., 2015; Westrich et al., 2017). The E7 oncoprotein of HPV may effect on TLR9 promoter through interfering in the NF- κ B pathway. Indeed, suppression of TLR9 expression leads to disturbing of IL-6 and IL-8 synthesis (Barros et al., 2018). In addition of IFN signaling, proapoptotic genes such as TNF-related apoptosis-inducing ligand (TRAIL) and X-linked inhibitor of apoptosis (XIAP)-associated factor 1 (XAF1), other RPRs (Retinoic acid-inducible gene I (RIG-1) and melanoma differentiation-associated protein 5 (MDA5) are also repressed by HR-HPV oncoproteins (Hasan et al., 2013; Reiser et al., 2011).

Fig. 2 TLR 9 signaling. TLR 9 is expressed on the surface of cells and recruited MyD88 lead to nuclear translocation of NF-κB in order to induce proinflammatory cytokines and type I interferon.

Adaptive immunity in papillomavirus infection

Both T-helper cells and cytotoxic T-cells (CTL) are representatives of cell-mediated immunity to repress HPV infection. T helper is included of two different phenotypes: T_{H1} and T_{H2} . There are differences in two subsets of T-helper cytokines. Actually, T_{H1} generates immune responses against intracellular infectious agents such as viruses and bacteria. On the contrary, T_{H2} is produced immune responses against extracellular pathogens (Steinbach and Riemer, 2018; Wakabayashi et al., 2019). The majority of T lymphocyte population in the cervical disorders in epithelium belongs to the subgroup of CD8 suppressor/cytotoxic T cells and the minority of them are CD4 helper/inductor subgroup. Initially, viral proteins present through antigen-presenting cells (APCs) by major histocompatibility class 1 (MHC-1) into the CTLs and destroy infected cells in this way (Wakabayashi et al., 2019; Gonçalves and Donadi, 2004). APCs of skin are divided into the Langerhans cells (LC) as the major population of immunity in the epidermis and dendritic cells (DC) in the dermis known as dermal DC (dDC). LCs which have langerin (CD207) as a receptor, are the only APCs which permeate in the dermis and inhabit there in the vicinity of infected keratinocytes (Hibma, 2012; Maarifi et al., 2020). It is obvious that the processed viral antigens in complex with MHC present to T cells receptors through DCs and activate them by multiplication of these cells. The activated $CD8^+$ T cells differentiate into CTLs and become the main source to produce perforin, granzyme, and proteolytic enzymes. Moreover, T_{H1} and T_{H2} are also differentiated from Activated $CD4^+$ helper T cells. T_{H1} generates IL-2, IL-12, IL-15, TNF- α , and λ -IFN whereas T_{H2} produces IL-4, IL-5, IL-6, IL-10, and IL-13 (Amador-Molina et al., 2013; Rosales and Rosales, 2014).

Role of adaptive immunity in the clearance of virus

T cells which express CD8 are known as cytotoxic T cells and predominantly induce perforin/granzyme in order to the contact-dependent mechanism to kill target cells (Litwin et al., 2021; Bhat et al., 2018). Ghosh et al. demonstrated that the predominant immune T cells in the case of cervical cancer were $CD8^+$ lymphocytes (Ghosh and Moore, 1992). It was also the same as in the study by Maskey et al. that showed infiltration of $CD8^+$ lymphocytes are greater than others in the epithelial layer of

positive HPV patients with normal cervical appearance (Maskey et al., 2019). Although, the reactivity of CD8⁺ to E6 as the oncoprotein in progressive stages of the majority of more patients with cervical cancer is predominant, but it is not the main response to viral clearance. In fact, this type of T cells have not been observed as a preventive response in front of tumor progression (Zhou et al., 2019). Nevertheless, a powerful CD4⁺ T cell response is necessary besides of CTL response in order to HPV clearance (Zhou et al., 2019). The relation between special types of papillomavirus and their clinical malignancies have revealed the significance of immune system functions and their ability to defend against viral disease (Steele et al., 2002). T cell responses are the most immunity in order to suppress papillomavirus infectivity because of the severe infection found in immunocompromised patients (Benton et al., 1992). Although keratinocytes of epithelial cells are triggered by HPVs as the main targets of infections, they are nonprofessional APCs. Actually, in normal condition with noninflammatory evidence MHC-II and other adhesions and stimulatory molecules such as CD80, CD8 and CD54 are not expressed by mentioned cells. Nevertheless, the keratinocytes may transfer antigen-specific signals toward T cells. The other cells within epidermal cells which known as LCs that previously mentioned above, are located upper the basal layer of proliferating keratinocytes. They are the professional APCs to capture papillomavirus antigens through macropinocytosis and receptor-mediated endocytosis on the surface of epithelial cells as the primary antiviral immune responses to papillomavirus infection (Steele et al., 2002; Sallusto et al., 1995). In cervical intraepithelial neoplasia (CIN), LCs diminution was found and it relates to the severity of the disease. In the former situation, LCs does not have detectable ability to express adhesion and stimulatory molecules and it suggests a poor condition of antigen presenting status. In contrast, the increased expression of these molecules in keratinocytes during severe disease accompanied with the accumulation of activated leucocytes under the lesion and development of CIN due to weak immune responses (Amador-Molina et al., 2013; Mota et al., 1999).

As a general rule, the main arm of immune response against intracellular agents and tumors is CD8⁺ T cells which activated due to receiving of presented antigens by MHC-I. Moreover, CD4⁺ T cells also interact with presented antigens with MHC-II and causing secretion of cytokines such as IFN γ and employment of macrophages following proliferation and activation of CD8 T cells (Farhood et al., 2019; Subbarayan et al., 2019).

Immune evasion mechanisms of human papillomavirus

Epigenetic modifications play a crucial role in carcinogenesis including deregulation of DNA methylation, histone modification, dysregulation of protein functions. Transcription factors are involved in various means of evading of normal host defense and establishing the infection in human by HPV (Westrich et al., 2017). HPV E5, E6, and E7 proteins account as viral factors to evade of immune responses (Song et al., 2015). The E5 protein is capable to dysregulate the expression of MHC in infected cells and leading to the escape of virus from the immune system. HPV-16 E5 may also down-regulate the ability of two cyclin-dependent protein kinase inhibitors (CKIs), p21 and p27, result in the progression of cell cycle and DNA synthesis (Campo et al., 2010; Venuti et al., 2011). Although expression of E5 protein in 60% of HPV-16 infected patients with cervical carcinoma were detected, its carcinogenesis characteristics are limited to the initial stages. In fact, in the progressive malignant cervical carcinogenesis the E5 protein was deleted when the genome of HPV is integrated (Venuti et al., 2011; DiMaio and Mattoon, 2001). The productions of tumorigenic genes, E6 and E7, are able to interact with p53 protein which known as tumor suppressor protein and promote transformation. Moreover, E7 protein has a high affinity to interact with Rb protein (Fig. 3) (Song et al., 2015; Faridi et al., 2011). E6 and E7 expression are essential for high-risk infection of HPV types and progression. They are capable to down-regulate expression of TLR 9 which is fundamental to present the antigen in cells. Moreover, enhancement of E6 and E7 expression may evade the attack of cytotoxic T cells (Hasan et al., 2013; Kim et al., 2013). Additionally, the E7 protein could down-regulate the expression of TLR 9 by histone modification though histone deacetylase HDAC1 and histone demethylase JARID1B (Hasan et al., 2013; Westrich et al., 2017). Both HPV 16 E6 and E7 oncoproteins contribute in deregulation of DNA methylation of the host DNA. In this manner, the induction of regulatory T (Treg) cells by HPV16 E7 mediates immune regression. Moreover, HPV 16 E6 represses IFN- κ which substantially expresses in keratinocytes and acts as an enhancer for the expression of IFN-stimulated genes (Westrich et al., 2017; Narayan et al., 2009).

HPV vaccination

The case of HPV is more manageable because of the small number of serotypes associated with severe disease and many do not cause problems. Thus, in this case, a significant impact on disease can be made by vaccinating against just a few of the many different genotypes. Both currently available vaccines contain HPV types 16 and 18 to vaccinate against cervical cancer, and the Merck vaccine contains, in addition, HPV types 6 and 11 to vaccinate against genital warts (*condyloma acuminatum*). The absence of efficient cell culture systems for HPVs originates the development of eukaryotic expression systems to produce virus-like particles composed of the L1 capsid protein, which are highly immunogenic. The development of a preventive virus-like particle (VLP)-based vaccine targeted to the human papillomavirus (HPV) types most often found in the cancers (Abdoli et al., 2013; Burd, 2003; Kianmehr et al., 2015). At this time, there are three HPV prophylactic vaccines based on L1 virus-like particles (VLPs) which are approved FDA for the prevention of cervical cancer with some limitations. Primary, HPV vaccines are type-restricted and expressing diverse L1 major capsid proteins. Next, the confirmed current HPV vaccines do not confer therapeutic effect and the third limitation is the relatively high cost of production that limited their broadly use in low-income settings, where about 90% of cervical cancer deaths happens. Hence, there is a vigorous need for an effective therapeutic vaccine through which HPV related neoplasia can be eliminated without

Fig. 3 E6 and E7 oncoproteins override regulation of cell cycle through p53 and pRB, respectively. E2F as a transcriptional factor is inhibited by pRB during the cell cycle. Indeed, phosphorylated pRB as an active form is detectable in G0-G1 phases and regulates cell cycle negatively. On the other hand, E7 leads to release of E2F during papillomavirus infection and permit to translate of cellular genes actively. Moreover, E6 is contributed with proapoptotic protein (p53) in the regulatory complex and degraded p53 to develop loss of tumoral suppression.

any invasive treatment (Karimi et al., 2020). The strategy of somatic gene therapy, the use of DNA as a therapeutic candidate and as a future, second-generation vaccine, is an excellent approach to open new horizon for medical applications. These vaccine will likely incorporate one or more of the additional oncogenic serotypes, such as 31, 33, and 35 (Stanley, 2014). Although, prophylactic vaccines offer an attractive promising vaccine for prevention of cervical cancer, but evidence suggests that the most of sexually active women presently remains neglected. High cost of the current vaccine strategies has encouraged researchers to continue to seek new methods of production and delivery in addition to preventive strategies (Ghaemi et al., 2010). The various therapeutic vaccine strategies remain of interest for majority of women who currently are infected. Several therapeutic strategies have focused on HPV E6 and E7 onco genes lacking the same success as the prevention trials. The most important candidate HPV vaccines are illustrated in Table 3.

Novel insight into the targeted therapies for cervical cancer

Structural and functional information concerning HPV proteins can offer novel insight into the mechanism(s) of cancer progression in the cervical epithelium. Recently, novel structural determinants of the interactions of viral proteins with their targets in keratinocytes have been elucidated. These exciting findings open the way for the development of targeted anti-oncogenic therapies, and may eventually allow the introduction of novel approaches for cervical cancer treatment. Delineation of the interactions of HPV oncoproteins E6 and E7 with their multiple cellular targets can provide the impetus for eventually targeted drug therapy for cervical cancer. The important differences between HPV structural proteins are responsible for different binding partners and offer insight into the mechanisms of HPV-mediated carcinogenesis. In particular, E6 and E7 proteins from high-risk HPV types are responsible for inducing uncontrolled cell proliferation. Only high-risk E6 and E7 bind p53 and of the Rb protein targets for ubiquitination and bypassing the G1/S checkpoint respectively.

These proteins can be used to enable researcher for the development of novel therapeutic targets besides new types of vaccines for prevention and cervical cancer therapy (Pappa et al., 2018).

Table 3 The FDA-approved and in development HPV vaccines.

FDA-approved Vaccines (Prophylactic vaccines)		
<i>Cervarix [2vHPV]</i>	<i>Gardasil [4vHPV]</i>	<i>Gardasil [9vHPV]</i>
HPV16&HPV18	HPV16, HPV18, HPV6&HPV11	HPV6&HPV11 HPV16, HPV18, HPV31&HPV33, HPV45, HPV52&HPV58
<i>Vaccine in development (Therapeutic E6&E7 based vaccines)</i>		
DNA/RNA based vaccine	Viral vector-based vaccine	Cell-based vaccine

In conclusion, insight from the genetic and epigenetic modifications at the regulatory region of HPV has contributed to the clarification of molecular mechanisms associated with HPV-related carcinogenesis that may open the way for the development of innovative therapeutic approaches.

Glossary

Arbovirus Arthropod-borne viruses that have replication in both vertebrate and arthropods and transmits between vertebrate animals by the bite of mosquitoes, ticks, etc.

Arthralgia Pain in joints.

Arthritis Inflammation and pain in joints.

Arthritogenic virus Medically important viruses causing inflammatory musculoskeletal disease.

Arthropods Invertebrates having external skeleton, capable of serving as vectors.

ELISA Enzyme-linked assays; immunological assay which is used to measure antibodies, antigens, glycoproteins, and proteins in the biological samples.

Hematophagous Feeding on blood.

Host Vertebrate which harbors the causative agent.

Myalgia Muscle pain.

RT-PCR Reverse transcription polymerase chain reaction; technique used to measure the amount of a specific RNA with an added step of reverse transcription of RNA to DNA.

Vector Living organism capable of transmitting disease to vertebrate hosts.

Virion Viral particle consisting of capsid and nucleic acid.

Introduction

Togaviridae (Chikungunya virus) and Flaviviridae (West Nile virus) arboviruses are among the emerging and re-emerging viruses causing various diseases since past decade. *Arboviruses* are arthropod-borne viruses that have replication in both vertebrate and arthropods and transmit between vertebrate animals through the bite of mosquitoes and ticks. Yellow fever was the first infectious disease transmitted via arbovirus to humans. Earlier, yellow fever virus (YFV) was cultivated in the laboratories and many other related arboviruses were isolated later on. These viruses were categorized into further two groups (Group A and B arboviruses) and were cumulatively named as “togavirus.” The word *toga* in *Latin* means “Roman cloak,” which provided the basis for the adoption of name *Togaviridae* as one of the viral families. Initially, family Togaviridae has two genera i.e. *alphaviruses* and *flaviviruses*. Flavivirus comes from word, *flavus* meaning “yellow” in Latin. The alphaviruses were those formerly known as Group A viruses. Likewise, flaviviruses were those formerly categorized as Group B viruses. However, flaviviruses are no longer categorized into family Togaviridae and are moved to family *Flaviviridae* (Schlesinger and Schlesinger, 2013). This re-classification resulted from the difference in genome, viral structure and morphogenesis of both families. Medically the most important group of arboviruses falls under the family Flaviviridae.

Viruses from both Togaviridae and Flaviviridae families are globally distributed and transmitted via animal vectors to humans. Transmission of arbovirus requires a particular *vector* and a *host* for every viral species. *Arthropods* are the invertebrates having external skeleton, capable of serving as vectors. Arthropods are hematophagous (feeding on blood) vectors carrying the disease causing agents. Host is a vertebrate which harbors the causative agent. Reservoir host is responsible for spreading the virus, and is of two different types i.e. primary and secondary. Primary reservoir host is responsible for indefinitely maintaining the virus in the epidemiologically connected populations. Secondary reservoir host transmits the virus into the target population but cannot maintain the virus in nature in the absence of primary host (Acevedo-Whitehouse et al., 2005; WHO Expert Committee on the Control of the Leishmaniases and World Health Organization, 2010; Artsob et al., 2017; Burrell et al., 2017; Duvall et al., 2018). In response to changes in societal factors such as population growth, tourism, increased commerce and urbanization leads to shift in epidemiology. Global distribution of Dengue virus, Japanese virus, West Nile encephalitis virus and Yellow fever virus is expanding i.e. Japanese encephalitis in Australia. Furthermore, clinical manifestations vary for different viral species.

Togaviridae family

Togaviridae family consists of single genus i.e. alphaviruses. Alphaviruses are highly diversified and globally distributed.

Classification of genera

Viral classification is based on characteristics of virion, nature of nucleic acid, viral envelope, and symmetry of capsid. The Togaviridae family has alphaviruses genus, which further consists of 31 species (ICTV, 2014). Furthermore, the viral species also differ by mode of transmission, antigenicity and ecological information. Alphaviruses can replicate in a variety of vertebrates, invertebrates and cellular cultures (Griffin, 2013, 2016).

Epidemiology and risk factors determining outbreak

Alphaviruses were originally isolated in the tropical regions of Africa, Asia and South America. However, alphaviruses are not detected in Antarctica due to absence of arthropod vectors. Furthermore, different viral species are distributed in different geographical locations.

Eastern equine encephalitis virus (EEEV) is the most virulent specie in United States causing encephalitis in equines. Sign and symptom appears between 3 and 10 days post-infection (Zacks and Paessler, 2010). EEEV is widely distributed in South America, Central America, Eastern coast of Canada, and Caribbean islands. EEV causes severe disease in humans, equines, pheasants, dogs and pigs. However, EEEV in humans is not commonly reported in United States. Furthermore, new cases were reported in Canada and east coast of United States. Similarly, in 2010 new cases were reported in Panama. Strains of EEEV differ in South and North America; with South American strains being more diversified. Furthermore, South American strains effect equines whereas North American strains are pathogenic for both equines and humans (Young et al., 2008; Vander Kelen et al., 2012; Weaver et al., 2012; Lubelczyk et al., 2013; Molaei et al., 2013; Go et al., 2014; Yu et al., 2015).

WEEV strains were initially isolated from equine in California in 1930 and later on from human brain in 1938. Primary host for WEEV are birds, secondary hosts are birds, pheasants and chickens and the dead-end hosts includes humans, equines and other mammals. Later on, viral species were found in South, North America and Caribbean. In Argentina, equine outbreaks were reported from the beginning of twentieth century followed by Brazil and Paraguay (Go et al., 2014; Hubálek et al., 2014).

Other WEEV complex viruses have different geographical distribution. HJV was identified in eastern United States; AURA was initially isolated in Brazil in 1959 and later on found in Argentina in 1966. VEEV was first isolated in Venezuelan followed by South and Central America, Caribbean islands, Mexico, Texas, Colombia, and Argentina. FMV are not pathogenic for humans, and was isolated in Oklahoma and Colorado (Steele and Twenhafel, 2010; Weaver and Reisen, 2010; Hubálek et al., 2014; Allison et al., 2015).

Epidemiological risk factors contributing in the outbreak of chikungunya includes not wearing full body covering clothes, sleeping nets, screening of doors and windows (with net), and uncovered water container which might promote larvae growth. Furthermore, being in contact with people with similar signs and symptoms can also be a risk factor for chikungunya spread (Alayu et al., 2021).

Structure

Alphaviruses are enveloped single-stranded RNA viruses. The lipo-protein viral envelope (host-cell derived structure) surrounds the viral capsid and has structural glycoproteins (E1 and E2) embedded on it. The viral capsid made by C protein contains the viral genome (Jose et al., 2009; Ruiz-Guillen et al., 2017). Genes for the structural protein is located at the 3' and for non-structural protein at 5' end of the genome. All the alphaviruses share their antigenic sites on the capsid (Griffin, 2013; Fig. 1).

Characteristics of members of Togaviridae family

Members of Togaviridae family have a diameter of 65–70 nm and replicates with in the cytoplasm (Table 1). Virus envelope comprises of glycosylated spike proteins (E1 and E2). Genome is enveloped and single stranded RNA having positive polarity. Translation of structural protein and non-structural protein occurs from sub-genomic RNA and genomic RNA, respectively.

Virus genus and disease

Togaviridae family comprises of genus alphaviruses. Earlier, togavirade has four genus with multiple species. In 1996, after genomic sequence analysis, arteriviruses were moved from Togaviridae to another family, Arteriviridae (Chen et al., 2018). In 1980s, due to similarity in genome organization, pestiviruses were also moved out to Flaviviridae family (Collett et al., 1988). In April 2019, Rubiviruses (Rubella virus) were classified into another family called Matonaviridae due to difference in their virion structure and gene expression as well. Currently, Togaviridae family only has alphaviruses (Brinton and Snijder, 2008; Chen et al., 2018).

Alphavirus

All alphaviruses (family Togaviridae) which causes diseases in humans are the arboviruses, being transmitted via hematophagous arthropods (Artsob et al., 2017; Duvallet et al., 2018). Alphavirus has approximately 31 species, out of which 8 species causes disease in both humans and animals (i.e. SINV, SFV, VEEV, EEEV, CHIKV, RRV, WEEV and ONNV) (Atkins, 2013). However, some of them rarely result in death i.e. chikungunya virus, Middelburg virus, Ross River virus, etc. In this chapter, alphaviruses are sub-classified according to the type of disorders they cause i.e. Neurotropic and arthritogenic or polyarthritis alphaviruses (Griffin, 2016; Contigiani and Diaz, 2017). Furthermore, alphaviruses will result in varying clinical manifestations. The viruses of clinical importance will be discussed in detail in this chapter.

Neurotropic alphaviruses

These causes disease typified with by fever, headache, malaise, neurological symptoms and/or encephalitis are Eastern equine encephalitis virus, Western equine encephalitis virus, Highlands J virus, Venezuelan equine encephalitis virus complex, Fort Morgan virus, and AURA virus.

Eastern equine encephalitis virus (EEEV)

EEEV is the most pathogenic and virulent alphavirus in United States. Moreover, highest mortality rate is reported in elderly population. Sign and symptoms appear between 3 and 10 days causing fever, myalgia, followed by encephalitis, coma and death. In equine, EEEV causes encephalitis starting with fever and anorexia. Furthermore, EEV is associated with myelitis, seizures, paralysis and death (Zacks and Paessler, 2010).

Western equine encephalitis virus (WEEV)

WEEV causes neurological diseases but with lesser severity as compared to EEEV in their signs and symptoms. Clinical manifestations of WEEV include fever, headache and meningitis. However, WEEV could be either asymptomatic or lethal too. Neurological signs are reported, including lethargy, tremors, dizziness, stiff neck, altered mental stability and irritability (Griffin, 2013).

Fig. 1 Alphavirus genome showing 5' cap, non-structural proteins (nsP1, nsP2, nsP3, nsP4), capsid, structural proteins (E1 and E2), and 3' end. Information taken from Sherman MB and Weaver SC (2010) Structure of the recombinant alphavirus western equine encephalitis virus revealed by cryoelectron microscopy. *Journal of Virology* 84(19): 9775.

Table 1 Characteristics of Togaviridae family.

Characteristics	Togaviridae
Virion	Spherical virion with single capsid protein and three glycoproteins; 65–70 nm diameter
Genome	Enveloped, single stranded RNA (10–12 kb), positive polarity
Replication	Cytoplasmic
Translation	From sub-genomic RNA (structural protein) and genomic RNA (non-structural)

Information taken from Chen R, Mukhopadhyay S, Merits A, Bolling B, Nasar F, Coffey L.L., Powers, A and Weaver SC (2018). ICTV virus taxonomy profile: Togaviridae. *Journal of General Virology* 99(6): 761–762.

Highlands J virus (HJV)

Highlands J virus (HJV) is pathogenic in ducks, turkeys, pheasants and other birds. HJV may cause equine encephalitis as well. In 1960, HJV was isolated from corvid and is a member of WEE complex distributed in eastern United States. Unlike EEEV, HJV is not pathogenic to humans. Furthermore, migratory birds are the host and *Cs. Melanura* was the vector in United States (Steele and Twenhafel, 2010; Griffin, 2013; Contigiani and Diaz, 2017).

Venezuelan equine encephalitis virus Complex (VEEV)

VEEV is a new world alphavirus found in human and equine. Symptoms of VEEV in human include fever, nausea, vomiting, myalgia and encephalitis. However, equines are presented with fever, depression, tachycardia, and anorexia. It is prevalent in Southern and Central America and has two sub-types (Weaver et al., 2004; Weaver and Reisen, 2010; Zacks and Paessler, 2010; Griffin, 2013):

- (a) Epizootic virus (IAB and IC).
- (b) Enzootic virus (ID, ID and IF).

Epizootic strains causes serious infection whereas enzootic strains cause mild infection. Epizootic strains are found in human and animals (rodents, dogs, sheep, and bats) with mosquitos as vector during out-break. The vectors involved in transmission depends upon the region i.e. *Aedes* and *Psorophora* in United States. Furthermore, epizootic viruses can cause serious infections. These are clinically undistinguishable from influenza and other viral diseases. The early stage (2–5 days) clinical manifestations are chills, fever, severe headache, sore-throat, retro-orbital pain, myalgia, nausea and vomiting. Later on, neurological symptoms are reported, including drowsiness, encephalitis, paralysis, coma and death (Weaver et al., 2004; Weaver and Reisen, 2010; Zacks and Paessler, 2010; Aguilar et al., 2011; Taylor and Paessler, 2013).

Fort Morgan virus (FMV)

Fort Morgan virus (FMV), isolated in North America, are non-pathogenic for both human as well as animals. In Oklahoma and eastern Colorado, these viruses were isolated from sparrows and swallows. Other closely related virus such as Buggy Creek virus (BCV) is similar to the FMV in its antigenicity (Griffin, 2013; Allison et al., 2015).

AURA virus

AURA virus has serological similarity with WEEV and sindbis virus. Aura virus is named after its isolation from a small river in Belém, Brazil. Moreover, AURA has similar sequence identity with the sindbis virus. AURA virus is isolated from *Aedes serratus* in northern Argentina and Brazil. Evidently no pathogenicity has been reported in human (Sabattini et al., 1998; Griffin, 2013).

Arthritogenic alphaviruses

Arthritogenic or polyarthritis alphaviruses are mosquito-borne viruses causing disease with symptoms including fever, rash and joint disorders (arthralgia) in the infected host. These viruses includes Chikungunya virus, Sindbis virus, Ross River virus, Semliki virus, O'nyong-nyong virus, Barmah Forest viruses, and Mayaro virus (Contigiani and Diaz, 2017).

Chikungunya virus (CHIKV)

Chikungunya virus (CHIKV) is the arbovirus first isolated in Tanzania in 1952. The word chikungunya means “which bends up” in Kimakonde/Makonde language and is associated with the distorted posture of patient. CHIKV is found in Asia, Europe, Australia, and Africa. It is one of the old world alphaviruses and is transmitted by mosquito (Contigiani and Diaz, 2017). *Aedes* species such as *Ae. aegypti* and *Ae. albopictus* are the vector mainly involved in transmission of CHIKV. The clinical manifestations of CHIKV in human are non-specific flu like symptoms, fever, rash and arthritis (Bettadapura et al., 2013; Caglioti et al., 2013; Faria et al., 2016).

In the endemic area, insect control and prevention from mosquito bites helps in the prevention of contracting CHIKV (Caglioti et al., 2013). Conventional and time loop-mediated RT-PCR is used for diagnosis purpose in the early days (Pfeffer et al., 2002; Parida et al., 2007). Different serological methods are used to detect the CHIKV-specific immune response (IgM and IgG antibodies) i.e. Enzyme-linked assays (ELISA) and immunofluorescence assays (IFA) (Sam and Abu Bakar, 2006; Litzba et al., 2008). CHIKV is

managed symptomatically with the help of NSAIDs, anti-pyretics and fluids to relieve, inflammation and fever. Faster resolution of arthritis and joint pain were observed after treating the patients with Ribavirin 200 mg (twice a day) for 7 days. Moreover, steroids are occasionally used in the course of treatment. However, effectiveness of chloroquine remains unclear (Ravichandran and Manian, 2008; Taubitz et al., 2007). Passive immunization can be used in humans after its successful results *in vitro* and *in vivo* (Couderc et al., 2009). A vaccine containing EMCV IRES (Encephalomyocarditis virus—internal ribosome entry site) sequence introduced into the CHIKV sub-genomic promoter, is in its pre-clinical trial phase (Plante et al., 2011). Various vaccines are developed but are still not licensed to use in humans (Caglioti et al., 2013).

Sindbis virus (SINV)

Sindbis virus (SINV) is one of the old world alphaviruses named after originally isolated near Sindbis in Egypt. SINV is associated with arthritis and rash (Grywna et al., 2010). SINV is commonly found in Egypt, East and South Africa, Philippines, Israel and Australia. The symptoms of SINV are arthralgia, fever and rash. SINV is the causative agent of Pogosta and Ockelbo disease (Jöst et al., 2010; Sane et al., 2012).

Other arthritogenic viruses

Other arthritogenic viruses are Ross River virus (RRV), Semliki Forest virus (SFV), Barmah Forest viruses, Mayaro virus (MAYV) and O'nyong-nyong virus (ONNV). RRV was first isolated in Ross River in Australia. ONNV in the Nilotic language means "weakening of the joints." SFV is known to cause disease in both human and animals. In 1942, SFV was first isolated from mosquito in a forest in Uganda (Smithburn and Haddow, 1944; Tables 2 and 3).

Transmission and viral life cycle

Alphaviruses are transmitted via mosquitoes and keeps on circulating in the nature via mosquito-vertebrate-mosquito cycle. Virus is contracted usually in the endemic area. Virus is released into the host and later on lysed (Ruiz-Guillen et al., 2017; Lim et al., 2018).

The alphaviruses are multiplied intracellularly via receptor mediated cytoplasmic endocytosis; the diagrammatic representation is presented in Fig. 2. As a result, sub-genomic RNA specie (26S RNA) is formed which codes for structural proteins. However, genomic RNA serves as mRNA for the non-structural protein. The non-structural protein forms the 2/3rd and structural protein makes up the 1/3rd of the genome (Mudiganti, 2007).

Clinical manifestation

Clinical manifestations of alphaviruses are fever, arthralgia, and rash and can also result in neurological disorders. However, immune system eliminates the virus, whereas other symptoms including arthritis prevails for a few weeks (Griffin, 2013, 2016).

Table 2 Important viruses and their characteristics.

<i>Virus</i>	<i>Associated syndrome/disease</i>	<i>Host</i>	<i>Vector</i>	<i>Geographical distribution</i>
Eastern equine encephalitis virus (EEEV)	Eastern equine encephalitis	Birds	Mosquitoes	South America, Central America, Eastern coast of Canada, and Caribbean islands
Western equine encephalitis virus (WEEV)	Western equine encephalitis	Birds	Mosquitoes	South America, North America and Caribbean, Argentina
Venezuelan equine encephalitis virus complex (VEEV)	Venezuelan equine encephalitis	Mammals, horses	Mosquitoes	South America, Central America
Chikungunya virus (CHIKV)	Chikungunya	Monkeys, humans	Mosquitoes	Asia, Europe, parts of Africa, Australia, and Europe
Ross River virus (RRV)	Ross River polyarthritis	Macropods and other mammals	Mosquitoes	Asia, Europe, parts of Africa, Australia, and Europe
Japanese encephalitis virus (JEV)	Japanese encephalitis	Birds, pigs	Mosquitoes	Asia, Australia
St. Louis Encephalitis virus (SLEV)	St. Louis encephalitis	Birds	Mosquitoes	South America, Brazil, Argentina, Panama
West Nile virus (WNV)	West Nile fever/ encephalitis	Birds	Mosquitoes	Africa, North America, Europe, and Asia
Yellow fever virus (YFV)	Yellow fever	Monkeys, humans	Mosquitoes	Africa, Latin America, Brazil
Dengue virus (DENV)	Dengue fever	Humans, monkeys	Mosquitoes	Asia, Africa, United States, Europe
Tick-borne encephalitis virus (TBEVs)	Tick-borne encephalitis	Mammals, birds	Ticks	Europe, Asia, North America, Japan, Siberia, and Saudi Arabia
Sindbis virus (SINV)	Pogosta and Ockelbo disease	Birds	Mosquitoes	Egypt, East and South Africa, Philippines, Israel and Australia

Information taken from Contigiani MS and Diaz LA (2017) Togaviridae. In: *Arthropod Borne Diseases*, pp. 115–135. Springer.

Table 3 Epidemiological features of important viruses and diseases caused by these viruses.

Disease	Causative agent ^a	Mode of transmission ^b	Incubation period (days)
Dengue	Dengue fever virus	Mosquito bite	5–8
Rubella	Rubella virus	Respiratory, congenital	17–20
Alphavirus encephalitis	EEEV, WEEV, VEEV	Mosquito bite	4–10
Hepatitis C	Hepatitis C virus	Parenteral, sexual	40–60

^aDisease causing viruses.

^bUntil the appearance of prodromal set of signs and symptoms.

Information taken from Burrell CJ, Howard CR, and Murphy FA (2017) Epidemiology of viral infections. In: *Fenner and White's Medical Virology*, pp. 185–203.

Fig. 2 Life-cycle of alphavirus. Alphavirus binds to the receptor and enters the cell by endocytosis. RNA is released after the nucleocapsid (NC) is transported into cytoplasm. Protein translation and RNA transcription from both genomic and sub-genomic RNA occurs and are eventually release. Adapted from Leung JY-S, Ng MM-L, and Chu JJH (2011) Replication of alphaviruses: A review on the entry process of alphaviruses into cells. *Advances in Virology* 2011: 249640.

Diagnosis

Viral detection and isolation are used to identify the virus and establish a valid diagnosis. Antibody titer of either IgM or IgG also helps in virus determination. Furthermore, reverse transcription polymerase chain reaction (RT-PCR) assay is also used for identification purpose against the panel of alphaviruses available in a geographical region, against the known virus i.e. CHIKV sera (Yap et al., 2010).

Disease management/treatment

Currently, there is no specific antiviral agent for the treatment of alphaviruses induced diseases. However, symptomatic management is indicated to overcome the symptoms. Non-steroidal anti-inflammatory drugs (Naproxen and Ibuprofen) and anti-pyretic agents (Paracetamol) are primarily used for fever and pain (Contigiani and Diaz, 2017).

Prevention

Virological, serological, entomological and epidemiological surveillance should be made a part of preventive program. Available vaccines should be used for passive immunization by the people traveling to endemic areas or the residents. Veterinary vaccines for WEEV and EEEV are being prepared. TC83 strain of VEEV is used successfully in horses as well as in military and laboratory staff. However, its use is still not recommended in general public (Go et al., 2014).

Flaviviridae family

Flaviviruses were originally classified under the Togaviridae family. Initially, there were virological and biological similarities between these two families. However, after years of research flaviviruses were separated from Togaviridae family on the basis of difference in the mode of replication and genetic organization (Chen et al., 2018).

Classification of genera

As per International Committee on Taxonomy of Viruses (ICTV) recognition, Flaviviridae have four genus flavivirus, hepacivirus, pestivirus and pegivirus (Simmonds et al., 2017).

Epidemiology and risk factors determining dispersal

Overall, flaviviruses are globally distributed with individual species restricted to some areas i.e. Dengue fever virus in tropical regions of Africa, Asia, Australia, America, and Oceania; Yellow fever virus in subtropical regions of South America and Africa (Simmonds et al., 2017).

However, dengue is associated with seasonal changes providing favorable breeding environment for the *Aedes* mosquitoes i.e. in optimum temperature, humidity, and rainfall. Over-crowded places and traveling from endemic to the non-endemic areas reportedly increased the spread of dengue virus. Other aforementioned risk factors for chikungunya spread are also applicable for dengue as well (Khan et al., 2018; Alayu et al., 2021).

Structure

Flavivirus are single stranded, positive sense RNA. Morphology of viruses in Flaviviridae family is somewhat similar with some changes in the spike proteins. They are spherical lipid enveloped RNA viruses with single core protein and 2–3 virus-coded glycoproteins. In case of *Flavivirus*, *Hepacivirus* and *Pegivirus* families, 2 envelope proteins are present. However, 3 envelope proteins are present in pestivirus family viruses (Lindenbach et al., 2013; Simmonds et al., 2017).

Characteristics of members of Flaviviridae family

Virions are 50 nm in diameter and are icosahedral in symmetry. Virion is positive sense single-stranded messenger ribonucleic acid (ssmRNA) and has a genome of 9–13 kb (Lindenbach et al., 2013; Simmonds et al., 2017; Table 4).

Virus genus and disease

Flavivirus genus has 53 species out of which commonly causing diseases in humans are YFV, dengue fever virus, West Nile virus, Japanese encephalitis virus, and Tick-borne encephalitis virus. Hepacivirus genus contains single specie hepatitis C virus (HCV) with 17 genotypes and 84 subtypes (Smith et al., 2014).

Flavivirus

Majority of the flaviviruses are transmitted to vertebrates via mosquitos and ticks. They are composed of capsid protein and 2 spike proteins. Flaviviruses are found globally, however, some species are only restricted to the epidemic and endemic areas i.e. dengue virus in tropical regions Asia, Africa, United States and Australia; YFV in subtropical regions of Africa and South America (Simmonds et al., 2017). Important human pathogens in flavivirus genus are Yellow fever virus, Dengue fever virus, West Nile virus, Japanese encephalitis virus, tick-borne encephalitis virus and St. Louis encephalitis virus.

Yellow fever virus

Yellow fever virus (YFV) is one of the initially identified virus which led to the further identification and categorization of the arboviruses (Simmonds et al., 2017). YFV was reported highest in Brazil during the outbreak of 2016–17. YFV is transmitted via *Aedes* spp. Mosquitoes (Faria et al., 2018). YFV is endemic in Latin America, and tropical forests of Africa. When effective control measures are not practiced, Yellow fever (YF) outbreak can occur i.e. in Republic of Congo and Angola in 2015–16. 20–30% patients with mild to moderate (viremic phase) YF presents with high fever, headache, myalgia, nausea, and loss of appetite for 2–4 days. Worsening of the viremic phase symptoms in observed in 15% of the infected patients (toxemic phase) followed by icteric discoloration of skin, bradycardia, neurological impairment, renal dysfunction, bleeding and cardiovascular dysfunction is reported. Furthermore, half of the infected patients are asymptomatic. Differential diagnosis is difficult in case of all the viral

Table 4 Characteristics of Flaviviridae family.

Characteristics	Flaviviridae
Virion	Spherical virion with single core protein and 2–3 enveloped glycoproteins; 40–60 nm diameter
Genome	Non-segmented RNA; positive sense 9–13 kb
Replication	Cytoplasmic
Translation	From genomic RNA containing type cap 1

Information taken from Chen R, Mukhopadhyay S, Merits A, Bolling B, Nasar F, Coffey L.L., Powers, A and Weaver SC (2018). ICTV virus taxonomy profile: Togaviridae. *Journal of General Virology* 99(6): 761–762.

diseases in their initial phase due to presentation of similar clinical manifestations. However, serological testing for IgM and IgG antibodies is recommended at day 5. However, till date no specific antiviral treatment is available for the treatment. Adequate hydration and dipyrone is used for symptomatic relief. There is an ongoing research for the use of sofosbuvir against YFV. YFV is the hemorrhagic fever which was considered a lethal disease before the vaccine was developed. Yellow fever vaccine (Live 17D vaccine; YF-Vax, Stamaril) is available and considered most potent vaccine ever developed. Immunization and vector control helps immensely in the prevention and further transmission of YFV (Johansson et al., 2010; Douam and Ploss, 2018). However, people traveling to endemic areas and those who are unvaccinated can still contract the YFV (Monath, 2001).

Dengue virus

Dengue virus (DENV) is transmitted via mosquitos of *Aedes* spp. Incubation period of DENV is an average of 7 days (3–14 days). There are four different types of serotypes: DENV-1, DENV-2, DENV-3, and DENV-4. DENV infects the human via *Aedes* spp. vector (*A. aegypt* and *A. albopictus*) found originally in Asia later spreading to Africa, United States and Europe. Clinical manifestations varies, commonly including fever, headache, arthralgia, and rash (Kularatne, 2015). Other identification signs are deranged LFTs, thrombocytopenia, leucopenia, hemorrhage and plasma leakage. There are different phases of infection i.e. febrile, critical and convalescent. The early diagnosis is by advising complete blood culture (CBC), thrombocytopenia and leucopenia are characteristics of the day followed by dengue fever. Identification of viral nucleic acid or antigen is evident during the first 5 days of infection (World Health et al., 2009; Kularatne, 2015). No specific anti-viral is developed or recommended for the management of DENV. Oral rehydration, intravenous fluids (i.e. lactated ringer or 0.9% normal saline), colloids (i.e. dextran 70% or 6% starch) are recommended for the management. Only acetaminophen should be used to treat fever and NSAIDs should be avoided to prevent any bleeding (Kularatne, 2015). However, prednisolone is reported to be used and not associated with the prolongation of viremia (Tam et al., 2012). Furthermore, platelet transfusion is only required in case of active bleeding. First vaccine against DENV, a live attenuated recombinant tetravalent dengue vaccine (Dengvaxia®) is under phase III trial. Dengvaxia (CYD-TDV) is a 3-dose vaccine with a 0–6–12 month schedule was registered in Mexico. Other type of vaccines are under development and trial phases including inactivated, DNA, and subunit vaccine (Rajapakse, 2009; Teixeira and Barreto, 2009; World Health Organization. Regional Office for South-East Asia, 2011; Deng et al., 2020).

West Nile virus

West Nile virus (WNV) is neurotropic flavivirus transmitted via mosquito bite to human. WNV is found in Africa, North America, Europe, and Asia. Of the infected patients, 80% remains asymptomatic. WNV cause acute systematic febrile illness common in all age groups i.e. West Nile Fever (WNF). Patient with WNF experiences fever, fatigue, headache, myalgia and gastrointestinal disturbances leading to dehydration. Neurological symptoms are manifested in some patients due to neuro-invasive disease causing infection of meninges mostly in younger age i.e. West Nile Meningitis (WNM). WNM is characterized by fever, headache, nuchal rigidity, photophobia, exacerbating head pain and GI symptoms. Acute polio-like syndrome is also caused by WNV causing the viral infection of horn cells of spinal cord i.e. West Nile Poliomyelitis. Furthermore, encephalitis is also caused by WNV mostly in elder age group, causing infection of brain parenchyma i.e. West Nile Encephalitis (WNE). However, clinical picture of WNM, WNE and WNP might overlap (Granwehr et al., 2004; Sejvar, 2014).

Japanese encephalitis virus

Japanese encephalitis virus (JEV) causes the most important viral encephalitis, Japanese encephalitis (JE) globally. JE has been spread to different parts of Asia and Australia (Unni et al., 2011). However, China still reports the 50% of the total JE cases. About 50% of the JEV infected patients develops neurological sequelae. However, 25% of the patients are expired after contracting JEV (Van den Hurk et al., 2009). Major reservoirs to harbor these viruses are mosquitoes, pigs and water birds. Primary vector for JEV are the mosquitoes i.e. *Culex* genus and *Anopheles* genus in India. Difference in epidemiology is due to genotypic and temperature variations. Majority of the JEV are asymptomatic, reporting mostly in children below 15 years. Clinical course of illness is characterized by fever, headache, backache, myalgia, GI disturbances and anorexia. These symptoms lasts for a week, followed by disturbance in gait, mental status, speech and motor functions. Furthermore, pathological abnormalities are reported in CNS (Fischer et al., 2010). No benefit was observed from the treatment with interferon- α (Solomon et al., 2003).

St. Louis encephalitis virus (SLEV)

St. Louis encephalitis virus (SLEV) causes St. Louis encephalitis (SLE), a viral epidemic in St. Louis, United States. SLEV is transmitted by mosquito species in *Culex* genus. Different genotypes are found in different regions i.e. Genotype III and V in South America, I and II in United States, IV and VI in Panama, VIII in Brazil and VII in Argentina. Clinical symptoms may vary from meningitis and meningococcal encephalitis. Furthermore, disease severity is associated with the patient's age. However, there are no specific treatment and vaccine currently available. Furthermore, management with INF and IVIG in suspected SLEV infected patients is recommended (Reisen, 2003).

Tick-borne encephalitis virus (TBEV)

Tick-borne encephalitis virus (TBEV) is the group of flaviviruses transmitted by the ticks as vectors. These tick-borne viruses results in different diseases in both human and animals, which ranges from fever, body ache, malaise, fatigue, encephalitis, meningitis, myelitis and hemorrhage. TBEV are found in Europe, North America, Japan, China, Russia, Siberia, India, and Saudi Arabia. TBEV is

diagnosed via cerebrospinal fluid (CSF) cell count, IgM and IgG, and enzyme-linked immunosorbent assay (ELISA) of TBEV detection. Furthermore, inactivated vaccine (FSME-IMMUN) is available in Europe but not licensed to be used in United States. No specific TBE treatment is available and only symptomatic treatment is provided with antipyretics, anti-emetics, analgesics, fluid and electrolyte replacement therapy (Hubálek and Rudolf, 2012).

Pestivirus

The word *Pesti* comes from a Latin *Pestis*, meaning “plague.” This genus of Flaviviridae family infects pigs, cattle, goats, sheep and wild ruminants. Pestivirus is transmitted via contaminated secretions. This genus has four species i.e. classical swine fever virus (CSFV), border disease virus (BDV) and bovine viral diarrhea virus 1 & 2 (BVDV). Other diseases associated with pestivirus genus are hemorrhagic syndromes, abortion, and fatal mucosal disease in animals. In this chapter, only CSFV is discussed in detail. Renaming of pestiviruses species are suggested i.e. Pestivirus A (BVDV-1), pestivirus B (BVDV-2), pestivirus C (CSFV), and pestivirus D (BDV). However, pronghorn pestivirus, Aydin-like pestivirus, rat pestivirus, APPV, Bungowannah virus, giraffe pestivirus, and Hobi-like pestivirus are new suggestions to be included into this genus (Simmonds et al., 2017; Kirkland et al., 2019).

Classic swine flu virus

Classical swine fever (CSF) is a viral disease of wild and domestic pigs and boars caused by classical swine fever virus (CSFV) (Luo et al., 2014). CSF occurs either as acute or chronic course of disease. In acute course fever, the typical clinical manifestations 1–2 weeks after contracting infection are fever, weakness, anorexia, gastrointestinal symptoms and conjunctivitis. Neurological disorder occurs 2–4 weeks after the infection. Some atypical symptoms including cyanosis on abdomen, limbs, and ears (Petrov et al., 2014).

Hepacivirus

Hepacivirus name is derived from Greek word *hepatos/hepar* meaning “liver.” These are single stranded RNA viruses having positive polarity, which codes for polyprotein. Human pathogen responsible for liver disease belongs to this genus of family Flaviviridae i.e. Hepatitis C virus (HCV). Hepacivirus causes both chronic and acute hepatitis, carcinoma and liver function failure. The pathogens in this group affect the liver and are widely distributed via rodents, bats, horses and dogs. This genus also includes other viruses which effects rodents, cows, horses and bats (Simmonds et al., 2017). Hepacivirus cause millions of infections presenting with fever, neurological and GI disease and hemorrhage. Chronic hepatitis leads to chronic hepatic fibrosis, cirrhosis and carcinoma. Till date there are no successfully effective vaccination available (Bukh, 2016).

Pegivirus

Initially, pegivirus was found in monkeys and humans. Then equine pegivirus, rodent pegivirus and bat pegivirus have been found since 2010. However, species of this genus are not associated with the disease or infection in mammals (Lu et al., 2016; Simmonds et al., 2017).

Transmission and viral life cycle

Most of the flaviviruses (i.e. Dengue, Yellow, Japanese, Nile, Zika and tick-borne virus) are horizontally transmitted from vector (i.e. mosquitoes and ticks) to vertebrate hosts. Primary vector of flavivirus are birds and mammals. However, some flavivirus are separated exclusively from vertebrates or mosquitoes and are vertically transmitted. Remainder of the virus is transmitted between bats and rodents (Valarcher et al., 2015; Simmonds et al., 2017; Wilder-Smith et al., 2017). Viral infection is initiated by mosquito or tick's bite. Furthermore, virus is dispersed into the host body during lytic infections of the cells (Simmonds et al., 2017).

Clinical manifestations

A variety of the clinical manifestations are presented which can be distinguished by the type of virus. YF is characterized by high grade fever, headache, myalgia, and nausea. However, dengue presents with fever, headache, arthralgia, and rash. Hepacivirus presents with fever, neurological and GI disease and hemorrhage. CSF causes fever, weakness, anorexia, gastrointestinal symptoms and conjunctivitis. JEV is clinically manifested with fever, headache, backache, myalgia, GI disturbances and anorexia. In WNF, fever, fatigue, headache, myalgia and gastrointestinal disturbances leading to dehydration are reported (Kularatne, 2015).

Diagnosis

Early stage differential diagnosis is quite challenging during the diseases caused by these viruses. Serological testing for IgM and IgG antibodies is recommended. However, acute phase of the disease can be identified via RT-PCR. Furthermore, viral infection and encephalitis caused by TBEV is diagnosed via cerebrospinal fluid (CSF) cell count, enzyme-linked immunosorbent assay (ELISA) of TBEV along with IgM and IgG.

Disease management/treatment

There is no specific treatment for the infections caused by viruses from Togaviridae and Flaviviridae family. The symptomatic management is provided to the infected patients through analgesics, anti-pyretics, anti-emetics and rehydration therapy. In some cases of suspected SLEV infected patients, INF and IVIG are used. However, no specific anti-virals against specific viruses are available till date. Management is described in detail under the individual headings of the diseases and causative agents.

Prevention

Detection and containment of viruses (i.e. YFV), requires epidemiological and genomic surveillance (Johansson et al., 2010). Furthermore, vaccination is another preventive measure which provides passive immunization against certain viruses. Table 5 summarizes the type and characteristics of vaccine against viruses of both Togaviridae and Flaviridae family. Vaccines against specific Flaviviridae family viruses are available i.e. YFV vaccine; the most potent vaccine available globally (Johansson et al., 2010; Douam and Ploss, 2018). CSFV vaccine is available and currently in use in China (Luo et al., 2014). An inactivated vaccine (FSME-IMMUN) for TBEV is available in Europe but not licensed in United States (Hubálek and Rudolf, 2012). Attenuated and inactivated vaccines for Japanese encephalitis are also available in certain parts of world (Van den Hurk et al., 2009). Furthermore, vaccine against dengue virus is under trial and development and their safety and efficacy profile will be available soon. However, vaccines against remaining Flaviviridae viruses are not available i.e. Hepacivirus (Rajapakse, 2009; Teixeira and Barreto, 2009; World Health Organization. Regional Office for South-East Asia, 2011).

Table 5 Type of vaccine and availability against Togaviridae and Flaviviridae viruses.

<i>Disease/virus</i>	<i>Vaccine type</i>	<i>Availability</i>
Eastern equine encephalitis virus (EEEV)	N/A	N/A
Western equine encephalitis virus (WEEV)	Inactivated (TSI-GSD 210)	N/A; trials
Highlands J virus (HJV)	N/A	N/A
Venezuelan equine encephalitis virus complex (VEEV)	Inactivated (C-84 strain)	N/A; phase II trials
Fort Morgan virus (FMV)	N/A	N/A
AURA virus	N/A	N/A
Chikungunya virus (CHIKV)	Subgenomic; ChAdOx1 Chik	Clinical trials; not licensed
Sindbis virus	Replicase-based DNA vaccine	N/A
Ross River virus (RRV)	Whole-virus Vero cell culture-derived	Phase III trial, unavailable
Semliki Forest virus (SFV)	N/A	N/A
Barmah Forest viruses	N/A	N/A
Mayaro virus (MAYV)	ChAdOx1 May, AdV-MAYV	Not licensed; unavailable but under trials
O'nyong-nyong virus (ONNV)	N/A	N/A
Yellow fever virus (YFV)	Live 17D (YF-Vax, Stamaril)	Available
Dengue virus (DENV)	Live attenuated recombinant (Dengvaxia)	Mexico
West Nile virus (WNV)	N/A	N/A
Japanese encephalitis virus (JEV)	Inactivated (JE-VAX), Inactivated Vero cell culture-derived (IXIARO), live attenuated (ChimeriVax-JE),	
St. Louis encephalitis virus (SLEV)	N/A	N/A
Tick-borne encephalitis virus (TBEV)	Inactivated vaccine (FSME-IMMUN)	Europe
Classical swine fever virus (CSFV); pigs	Live attenuated; Ingelvac (CSF MLV)	China
Hepatitis C virus (HCV)	N/A	N/A

AdV, adenovirus V; N/A, not available.

Conclusion

Flaviviridae and Togaviridae families contain important disease causing agents which contribute to high economic burden across the globe. These viruses cause diseases in both humans (Dengue, YF) and animals (CSF). Spread and re-emergence of alphaviruses is increased due to increased trade and tourism. Lack of specific antiviral treatment and immunization against these are currently the pressing concern. Intensive research is required to evaluate the effectiveness of repurposed drugs or specific antiviral agents in animals as well as humans. However, vaccines for some viruses are available (i.e. YFV, DENV), under clinical trials (i.e. CHIKV, VEEV, RRV) but unavailable, and developed for study purposes but unlicensed to be used (i.e. MAYV). Unavailability of the already developed vaccines (i.e. Dengvaxia®) globally is another pressing concern which needs to be addressed at political and government level. A thorough understanding of epidemiology, biology, and genetic variability will result in improved diagnosis, prevention and treatment of the disease caused by these viruses. Furthermore, vigilant surveillance, epidemiological studies, and updated geographical data should be conducted and readily available to improve the current disease scenario.

Introduction

Hepatitis or inflammation of the liver is caused by many infectious agents, including viruses and non-infectious factors such as metabolic agents. Although the causes of viral hepatitis are numerous, the five major viruses are known to be the viruses that cause disease exclusively in the liver. Among these, hepatitis B, C and D viruses are known as infectious or serum hepatitis and hepatitis A and E are known as gastrointestinal hepatitis. The criteria for this classification are mainly based on the mode of transmission and their pathogenesis, so that infectious hepatitis is usually caused through blood or sexual transmission and gastrointestinal hepatitis through oral-fecal route. Acute infection with infectious hepatitis is usually asymptomatic and may occur depending on age and host factors, while in gastrointestinal hepatitis the symptoms of acute hepatitis are more common (Khuroo and Sofi, 2020).

Hepatitis B virus (HBV)

Virus character

Hepatitis B virus is a member of the hepadnaviridae family that has a spherical structure with a semi-double stranded circular DNA genome (Fig. 1). The virus genome encodes five proteins called surface protein (S), core (C), polymerase (P), secretory protein (e), and a regulatory protein called X. Of the five virus proteins, three are important in diagnosis. The most important of these proteins is

Fig. 1 Schematic structure of HBV.

the surface antigen, called HBsAg, which is produced in large amounts during virus replication. Although this protein is present in three different structural forms called S, preS1 (M) and preS2 (L), it is referred to as HBsAg only in the diagnosis. The second protein is core, which forms the virus capsid and is identified as HBcAg. The diagnostic significance of this protein is that it is produced only during replication and intense activity of the virus. The e protein (HBeAg) is also produced during the replication of the virus and due to its secretory nature, leaves the cell and is able to stimulate the immune system and produces specific antibody (Rybicka and Bielawski, 2020; Knipe and Howley, 2013).

Route of transmission

The main routes of HBV transmission are:

- Exposure to contaminated blood and blood products.
- Sexual ways.
- Vertically (from mother to fetus) through placenta and milk (Hou et al., 2005).

Clinical manifestations

The incubation period of the disease varies from 6 weeks to 6 months. The acute course of the disease is asymptomatic in a high percentage of infected people. The incidence of symptoms increases with age, so that in children 10% and in adults 50% of infections have clinical symptoms. If symptoms occur, acute infection is associated with an increase in ALT of more than 500 IU/L and jaundice. Hepatic complications are generally caused by the destruction of liver cells by the cytotoxic activity of immune T cells. Cases of fulminant hepatitis and death occur in less than 1% of infections. About 95% of adults clear the virus within 6 months, but if the person is unable to clear the virus, the infection will become chronic.

Chronic infection refers to a condition in which the virus has been active in the body for more than 6 months, which can be confirmed by the presence of various viral factors. The most important of these factors is HBsAg, which is considered as a determining factor in infection and chronic disease (Kasper et al., 2015). Depending on the level of virus activity and virologic markers, chronic patients are divided into different groups.

Types of chronic HBV

Inactive carriers

In these individuals, also known as carriers in brief, HBcAb and HBsAg are positive, but the virus DNA level is not detectable or less than 10,000 copies per milliliter or 20,000 international units per milliliter. Liver enzymes are also normal.

Chronic hepatitis

In these people, in addition to HBsAg, HBeAg is also positive and the amount of virus DNA is more than 100,000 copies per milliliter. The liver biopsy shows a score greater than 4 and the level of liver enzymes is also permanent or periodically high (Hadziyannis and Laras, 2018).

Infants born to an infected mother (immune tolerance)

Infection in fetus or at early stages of the life is usually transmitted from an infected mother, especially in cases that the mother is HBeAg positive. This type of chronic infection is called immune tolerance status due to the lack of immune system development (Cryer and Imperial, 2019). In this case, HBeAg is positive and the amount of DNA is more than 20,000 IU/mL, but because of no destruction of liver cells by the cellular immune system, the enzyme alanine aminotransferase is normal. Liver biopsy of these individuals is usually without signs of inflammation and fibrosis. Due to the high amount of serum DNA, these people are highly contagious (Tran, 2011).

Occult hepatitis

Occult hepatitis is a condition that the virus DNA can be detected in liver or serum in the absence of HBsAg. The gold standard for this condition is DNA virus detection in the liver, but for the convenience of clinical cases, blood samples are used. It is important to note that most commercial HBsAg detection kits are able to detect all types and sub-types of virus, but may not be able to detect mutations in the S region of the virus, so it should always be considered that the hepatitis report in cases of a mutated S, may be false positive (Raimondo et al., 2019).

Laboratory diagnosis

HBsAg is the most important serum marker for diagnosing HBV infection. The presence of HBsAg indicates infection and the person is infected as long as HBsAg or HBV DNA can be detected in the blood. In addition to the S antigen, the presence or absence of HBeAg in the serum can determine severe or mild infection. The presence of this antigen indicates a high infection in the individual, while the presence of the e antibody indicates a low or no infection in the blood. However mutations in the virus that lead to the lack of core expression (core mutants) or pre-core mutants, despite the inability to detect HBeAg in some individuals, large amounts of the genome is present in the blood, so the presence of DNA is a more accurate measure of infectivity. Anti-HBc IgM is important in detecting acute infection, although it has also been seen in cases of active chronic infection (Fig. 2). The presence of this antibody in the absence of HBsAg indicates recovery from an acute illness and is one of the criteria for differentiation of immunity caused by infection or vaccination (Coffin et al., 2019; Gerlich, 2013).

Fig. 2 Serologic markers in acute (A) and chronic (B) HBV infection.

Applications of hepatitis diagnostic tests

Hepatitis B diagnostic tests are used for a variety of reasons:

1. In order to identify the disease in cases of suspected acute hepatitis. In the hepatitis diagnostic panel, along with hepatitis A and C, two tests of HBsAg and IgM against the core antigen (HBcAb) are performed. If HBsAg is positive, the person has hepatitis B. In rare cases, core IgM antibody (Anti-HBc) are the only indicator of infection, depending on the time passed from infection. During the early stages of recovery or the S window period, in which both the antigen and the antibody are negative, this antibody is the only indicator of infection. If HBsAg is positive and HBc IgM is negative, it indicates a chronic infection, and if HBsAg is negative, it indicates a past infection and recovery.
2. To assess the immunity against HBV. Immunity against hepatitis B is obtained through vaccination or recovery from the disease. In 90 to 95% of cases, vaccinated people develop antibodies against the virus that last for 5–10 years. The hallmark of immunity is the presence of antiHBs greater than 10 IU/mL. To distinguish immunity induced by vaccination from infection, antibodies against core virus (antiHBc) are used, which are only positive in people who have been exposed to the virus (Shih et al., 2018).
3. In order to identify chronic forms of the disease and follow the treatment process.

Chronic infection refers to the presence of HBsAg in the blood for more than 6 months, so if the S antigen is negative, the possibility of chronic infection is ruled out. Hepatic alanine aminotransferase (ALT) should be measured frequently if a person is diagnosed with a chronic condition. Permanent or intermittent high level of this enzyme indicates liver disease. It is important to note that the amount of this enzyme varies with age and sex, and in some cases, even with acute liver disease, there is no increase in ALT (EASL, 2017).

Interactions between hepatitis B virus and host immune system

Earlier studies failed to detect innate immune response such as IFNs in the early stage of HBV infection, so HBV was considered as a “stealth pathogen” that could establish persistent infection in hepatocytes by evading the host innate immune system (Kuiper et al., 2020). However, several lines of evidence have been questioned this property of the virus because it has been reported that HBV antigens directly trigger cellular immunity but using some mechanisms avoid recognition by the innate immune system. For instance, it is observed the interferon-stimulated genes (ISGs) expression is induced in the liver of infected chimpanzee model and HBV was unable to interfere with host cellular gene transcription (Megahed et al., 2020).

Furthermore, it has been shown that in the early phase of infection, HBV replication is suppressed in an interferon-independent manner. TLR2 senses HBV particles and leads to production of some inflammatory cytokines such as IL-6, IL1B and TNF. This hepatic innate response in addition to limit HBV replication, organizes adaptive immune responses. On the other hand, some studies indicated that during acute phase before the peak of viremia, HBV infection did not induce strongly the Toll-like receptors, pathogen recognition receptors (PRR) pathways, and production of IFNs but did trigger expression of the anti-inflammatory cytokine IL-10 that may contribute to the establishment of intrahepatic immune tolerance (Broering et al., 2020).

During the activation of the innate immune response, PRRs recognize viral RNAs and Toll-like receptors (TLR3, 7, 8, and 9) detect HBV RNAs in the endosome. After the activation of nuclear factors such as IRFs, NF- κ B and other transcription factors, a large array of genes involved in immune and inflammatory responses are induced and affect HBV replication and assembly. Suppression or defect of the involved receptors and signaling pathway lead to persistence of HBV. The evidence provided that HBV replication can inhibit PRR functions and target the TLR system, therefore, attenuate the anti-HBV innate immune responses. Thus, in the liver microenvironment HBV might has strategies to escape of the host innate immune system and it can counteract the innate responses. For example, HBx protein acts as a deubiquitinating enzyme which targets and disrupts RIG-I pathway and down regulates MAVS. HBV polymerase inhibits IFN-regulatory factors (IRF) activation in response to TLR3 and HBV precore/core proteins inhibit myxovirus resistance A (MxA) gene expression (Tang et al., 2018).

Overall, there are contradictory reports about HBV infection and host innate immunity. Different HBV genotypes induce different levels of innate immunity response. It is critical similarity of the innate immunity response in experimental models and primary human hepatocytes (Broering et al., 2020).

Adaptive immune responses are observed in patients with self-limited HBV infection. The studies showed that T CD8⁺ cells play an important role in the clearance of HBV and T CD4⁺ cells facilitate the induction of T CD8⁺ cells. Additionally, B cell-mediated humoral immune responses limit viral spread from HBV infected hepatocytes that are not eliminated by the T CD8⁺ cells. Nevertheless, patients with chronic hepatitis B (CHB) have defects in immune response which results in persistent viral replication and liver inflammation. Several mechanisms contribute to the weak adaptive immune responses during CHB in which characterized by (1) high HBV DNA, HBsAg, and HBeAg levels which induce HBV-specific immune tolerance, (2) exhaustion and dysfunctions of HBV-specific T cells under sustained HBV antigens stimulation, (3) disorder and decreased numbers of DCs and NK cells, (4) enhanced expression of immune checkpoint proteins, (5) intrahepatic inflammatory reactions can suppress the ability of HBV-specific T cells to access the infected liver parenchyma, (6) some enzymes such as arginase that is released from damaged hepatocytes cause depletion of the arginine which is essential in maintaining T cell functions and TCR-pathway dysfunction due to down-regulating of the CD3z signaling molecule, (7) T regulatory cells, B cells, and stellate cells infiltrating the hepatocytes can

secrete suppressor cytokines, such as TGF- β and IL-10 (Bertoletti and Ferrari, 2016). In general, despite the studies, there are still many complexities regarding immune responses against HBV that remain unknown.

Hepatitis D

Virus character

Hepatitis D or delta is a defective infectious agent that depends on the presence of hepatitis B surface protein for replication. The virus has a negative single-stranded RNA genome that forms a rod-shaped structure due to the complementarity of a high percentage of nucleotides with each other. The virus encodes two proteins called L and S that are different at the carboxyl terminus. The only detectable antigen of the delta virus is the smaller type of antigen (HDVAg or delta Ag) which forms the capsid of the virus (Knipe and Howley, 2013).

Clinical manifestations

Because the virus is unable to reproduce and cause infection without the presence of hepatitis B, infection with the virus is only seen in patients who are infected with HBV. Accordingly, two types of infection may occur:

HBV and HDV Co-infection. In this case, a susceptible person is exposed to both viruses at the same time, and both viruses cause infections. Co-infection with these two viruses generally results in acute hepatitis and clearance of both viruses from the body.

Super-infection with HDV. If a person carrying the hepatitis B virus becomes infected with HDV, it can cause acute hepatitis caused by HDV. Hepatitis D, like hepatitis B, can clear the body after an acute infection or lead to a chronic infection. In the second type of infection, the virus usually stays in the body chronically (Fig. 3). The rate of HDV infection in hepatitis B carriers varies from 70% to less than 1% in different geographical areas. So far, eight different genotypes have been identified for this virus, one of which has a global distribution and is divided into two subgenome "a" and "b". Genotypes 2–8 are limited to more specific regions. Different genotypes are different in terms of pathogenicity, so that genotype 3 is the most common cause of acute hepatitis, but genotype 2 usually does not cause specific pathological changes in the liver (Negro, 2014).

Diagnosis

Infection is detected by measuring IgG against delta antigen. IgM is not always produced in acute infection, but if it is produced, it can confirm acute infection.

IgM is detected during the window phase, the time between the appearance of delta antigen and the detection of IgG. If the infection progresses to a chronic infection, the amount of this antibody increases, so tracking this antibody indicates that the disease is progressing to a chronic disease. Recognition of the virus by molecular methods is the best marker of infection, and by quantitatively measuring the virus genome, the effectiveness of treatment can be assessed so that if the HDV virus is reduced by at least 5 log copies/ml during treatment for hepatitis B, it indicates successful treatment (Botelho-Souza et al., 2017).

Interactions between hepatitis D virus and host immune system

There are only a few models available to study HDV infection in human hepatocytes and the interactions between HDV with the immune responses. Despite the very limited coding capacity of HDV genome, it has mechanisms to escape immunity. Because of the HDV genome replicates in the nucleus and its circular RNA genome, the virus is able to avoid PRR binding and not to activate RIGI (Jung et al., 2020). Although, viral actions trigger immune responses via MDA-5 but HDV immune recognition still needs to be identified and it is not clear if HDV activates IFN signaling pathways in infected patients.

Fig. 3 Consequences of super/co infection of HDV and HBV.

Adaptive immune responses in HDV infections are weak and defective. Since the virus expresses only two proteins, S-HDAg and L-HDAg, with largely overlap in their protein sequence, few epitopes can be identified by T cells. On the other hand, HDV-specific helper T-cell expresses cytokines such as a high frequency of IL-10, IFN- γ , and IL-2 that stimulates cytotoxic T CD8⁺ cells to proliferate. In consequence, cytotoxic T-cells destroy HDV-infected cells. IFN- γ stimulates killing by macrophages and also induces CXCL-10 which recruits NK cells, dendritic cells, T-cells and macrophages to destroy infected cells and causing the more severe course of liver diseases in patients with HDV-chronic infection (Abbas and Afzal, 2013).

It has also been reported that L-HDAg provoke a sustained activation of the innate defense mechanisms. Therefore, the liver damage due to chronic HDV infection seemed to be immune mediated.

Co-infection with HBV must be beneficial for HDV. Indeed, HBX protein down regulates MAVS-induced signaling. Various studies reported HBsAg promotes to activate STAT3 and NF- κ B signaling that causes ER stress and induces the production of reactive oxygen species (ROS), hence, activates DNA methyltransferases, (it can silence the tumor suppressor genes) that might be necessary for induction of L-HDAg translocation from nucleus to cytoplasm in order to viral assembly and persistence of HDV. Thus, it has been proposed HBV prevent the innate immunity and make the cellular conditions favorable for HDV infection (Giersch and Dandri, 2015).

Hepatitis C virus

Virus characters

HCV is an enveloped virus with a positive polarity single-stranded genome from the Flaviviridae family. So far, seven genotypes and a number of subtypes have been identified. Genotypes one to three are globally distributed, while genotypes four and five are found mainly in Africa and limited parts of Asia, and genotype six in Asia. Genotypes are each divided into subtypes like 1a, 1b, 3a and 3b. The genome of HCV encodes 10–11 proteins, of which the core proteins, E1, E2, and possibly P7, are involved in the formation of the virus structure, and the rest are non-structural (NS) regulatory proteins. Protein E, which is produced by changing the reading frame of the core protein, is also considered non-structural. There are non-translating regulatory segments at both ends of the genome that can be used to detect viruses (Knipe and Howley, 2013).

Route of transmission

Transmission of the virus is mainly done through the following ways:

- Transfer of contaminated blood and blood products. Today, with the screening of blood and blood products, transmission through this route has sharply decreased.
- Using shared syringes in drug abusers. This method is one of the most important ways of transmitting the disease.
- Nosocomial infections. If medical equipment is not sterilized properly, it can transmit the disease. Patients undergoing renal dialysis are also prone to infection.
- Accidental infection in case of contact with contaminated blood.
- Tattoos and ear piercings.
- Sexual transmission.
- Vertical transfer from mother to fetus (Alter, 2011).

Clinical manifestations

The incubation period varies from 2 weeks to 6 months. About 60–70% of acute infections are asymptomatic, and in a percentage of people the symptoms include only lethargy, loss of appetite, nausea, and abdominal pain. Symptoms of jaundice are seen in only a few percentage of people. About 20% of patients with acute infection recover, but in 70–80% of cases the virus remains chronically in the body, in which there is no specific symptom of the disease and in some people there are nonspecific symptoms such as lethargy and fatigue. In 20–30% of people, after 20–30 years, the liver progresses to cirrhosis. Age, male gender, alcohol consumption and concomitant infections with other liver infecting agents can contribute to the aggravation of the disease (Wiktor, 2017).

Diagnosis

In general, HCV tests are divided into two main groups: screening and confirmatory tests. Screening tests only detect antibodies and do not distinguish between past, present, or chronic infections. Confirmatory tests diagnose the patients having an active infection.

Despite the high specificity of immunoassay screening tests, false positives are seen especially in pregnant women, people with immunological or blood diseases, and when the test is performed in low-risk communities.

False negatives are also seen in people with suppressed immunity, people with chronic kidney failure, dialysis, and the early stages of HCV infection. In such cases, especially in communities with a low prevalence of the disease, a complementary test is recommended to verify the initial results (EASL, 2020).

Fig. 4 Serologic markers in HCV infection.

Molecular tests. Serological tests cannot distinguish active infection from past infection. For this reason, a molecular confirmation test is necessary to confirm positive serological results. The viral RNA can be detected in the blood 1–3 weeks after infection and 1 month before the antibody appears (Fig. 4). Virus genome identification is the gold standard of diagnosis in ELISA positive subjects (Fabris et al., 2008).

Tests based on the detection of core antigen have also been designed, the amount of changes in core have shown a good correlation with the load of the virus genome (Chevaliez, 2019; Seme et al., 2005).

Interactions between hepatitis C virus and host immune system

Innate and adaptive immune responses play an important role in determining the viral clearance or progression to chronic infection. Upon HCV infection, the virus immediately activates intracellular pathogen recognition receptors (PRRs) including protein kinase R (PKR), toll-like receptors (TLRs), nucleotide-binding oligomerization domain (NOD)-like receptors (NLRs), retinoic acid-inducible gene-I-like receptors (RLRs), RNA helicase retinoic acid inducible gene I (RIG-I) and melanoma differentiation-associated gene 5 (MDA5). These receptors recognize viral pathogen-associated molecular patterns (PAMPs) which trigger different signaling cascades of the intracellular innate immune defense to induce interferons (IFNs) and the pro-inflammatory cytokines genes expression (Ferreira et al., 2020).

HCV also interferes with the adaptive immune system. There has been controversy over the role of humoral immune responses in the outcome of HCV infection. It is demonstrated that HCV clearance was associated with early appearance of neutralizing antibodies (nAbs) in the early phase of infection. In contrast, despite the production of antibody against HCV, during chronic infection, the escape variants of HCV are generated due to the selective pressure exerted by nAb responses (Lapa et al., 2019). It is known that HCV clearance is associated with a strong T-cell CD8⁺ and CD4⁺ response. In patients with persistent infection CD8⁺ cytotoxic T cells are relatively few and these cells recognize fewer epitopes (Tomer and Arora, 2020).

HCV via a number of mechanisms is able to impair the functional cells of immune system or subvert the host immune response resulting in establish a chronic infection. In fact, multiple HCV proteins including core, NS3/4A, NS5A, and NS5B counteract innate immune response by suppression of IFN induction. RIG-I/MDA-5, an intracellular sensor of double-strand RNA, binds to HCV RNA to induce IFNs via a mitochondrial antiviral signaling protein (MAVS) dependent pathway. Another major signaling pathway is mediated by TLR3 resulting in IFN induction. TLR3 is a membrane bound sensor of double-strand RNA which relays the signal downstream to the TRIF adapter. The NS3/4A serine protease of HCV blocks these signaling pathways by cleaving two intermediates, MAVS and TRIF. The result is suppression of IFN induction. NS5A independently interferes interferon action as well in some ways, it acts as antagonist of interferon, binds to PKR during late stages of replication and also induces the IL-8 expression which inhibits the activity of IFN. Beside, E2 glycoprotein directly bind to PKR to regulate its activity. Core protein in monomeric form activates TLR2-MyD88 pathway which it impairs core-TLR interaction. Thus, these particles are not sensed by TLR2. This activation of TLR2 pathway by the monomeric core protein causes the decrease of cytokine responses to TLR ligand and facilitate persistence of HCV infection. Some mechanisms have been suggested for the failure of the adaptive immune responses and persistence of infection. In principle, HCV-specific neutralizing antibodies are not long-lasting even after virus clearance and have a limited role in the control of infection. E1 or E2 glycoproteins-specific antibodies have virus-neutralizing activity. However, the antibodies tend to lose their activity as a result of virus escape mutations (Stuart et al., 2020; Imran et al., 2012).

Interaction of E2 envelope glycoprotein with CD81 leads to polyclonal B-cell activation followed by proliferation of monoclonal antibody (Tomer and Arora, 2020). The expansion of B-cell clones is a major factor in the immunopathogenesis of chronic infection. Interactions of HCV glycoproteins with the scavenger receptor B1 (SCARB1) and high-density lipoprotein (HDL) may protect from neutralizing antibodies. Furthermore, HCV may escape neutralization antibodies by cell to cell direct transmission (Heim and Thimme, 2014).

In acute HCV infections, virus-specific T cells have a crucial role in determining the outcome of virus persistence. Prolonged exposure to virus antigens causes exhaustion of CD8⁺ T cells and functionally the cells are impaired, and characterized by the up-regulation of different inhibitory receptors such as programmed cell death protein (PD1) and cytotoxic T lymphocyte antigen 4 (CTLA4). Under these conditions, the HCV infection progresses to a persistent chronic infection (Mauss et al., 2020).

Hepatitis A

Virus character

The hepatitis A virus is a member of the Picornaviridae that is a nonenveloped virus with positive single-stranded genome. The surface of the virus consists of four different structural proteins called Vp1-Vp4. Hepatitis A is prevalent in all of the world and along with hepatitis E are responsible of foodborne viral hepatitis through the world (Di Cola et al., 2021). In developing countries, 80–90% of children under the age of five have antibodies against the virus while in industrialized countries only 20–5% of children have specific antibodies (Koff, 1992).

Clinical manifestations

The incubation period of the disease is 3–5 weeks. Although the main target of the virus is hepatocytes, due to the gastrointestinal nature of the disease, the gastrointestinal tract appears to be the first site of virus replication. The virus is excreted in the feces from the end of the incubation period and with less intensity than in the middle (Iorio and John, 2020).

Diagnosis

The virus has a serotype and is detected by serological methods. The presence of IgM, which is measured by ELISA, indicates a recent infection, and IgG, indicates past infection. IgM is usually produced up to 10 days after exposure to the virus and peaks after about 4–6 weeks. IgG and IgM can be detected simultaneously 1–2 weeks after the onset of symptoms. If only IgG is positive, it indicates an infection more than 6 months ago because IgM remains in the body for about 4–6 months (average 48–63 days). Virus-specific IgA, which plays an important role in controlling gastrointestinal disease, is also produced following the acute phase.

Viral antigens can be detected in feces, serum, saliva, and cell culture (Abutaleb and Kottilil, 2020).

Molecular methods. Virus genome tracking is the most sensitive method of detecting the virus and appears in the blood before antibody detection and can be checked for a long time during recovery. RNA can also be detected in the stool, although serum is commonly used due to inhibitors such as bile salts, complex polysaccharides, and hemoglobin breakdown products present in the stool. Using PCR, the disease can be detected in the early stages and in the period of the antibody window, especially in the sudden occurrence of the disease.

Interactions between hepatitis A virus and host immune system

Serum HAV RNA level immediately increases after infection. The cytosolic RNA of HAV is sensed by MDA5. Although, the acute HAV infection resolves and does not progress to chronic infection, the studies showed the stimulation of IFN responses and the hepatic expression of ISGs is minimal that can be explained by the high level of viral replication or the disappearance of plasmacytoid dendritic cells (pDCs) (pDCs produce the cytokines including IFN- α by sensing enveloped HAV) from the infected liver after HAV-peak viremia. Indeed, HAV uses several strategies to interfere with the innate immune response. For example, 3ABC viral protein proteolytically cleaves the MAVS and 3CD eliminates TRIF (downstream of TLR3), 3Cpro also cleaves NEMO (NF- κ B essential modulator), thereby attenuates activation and IFN expression (Shin et al., 2016).

In both HBV and chronic HCV infection NK cells have a dual functional, reduced IFN γ production and maintained cytotoxicity, which might contribute to liver injury. It is noteworthy that these functions of NK cells have not been characterized in HAV infection. Also, neutralizing antibodies develop during self-limited infections and provide life-long protective immunity. After convalescence from acute hepatitis A, CD4⁺ T cell responses seem to be important for the resolution of HAV. Overall, acute HAV resolves and does not progress to chronic infection (Walker, 2019).

Hepatitis E

Virus character

Hepatitis E virus is a nonenveloped virus with positive RNA genome that causes a disease similar to hepatitis A. The virus has five main genotypes (HEV1-HEV4 and HEV7) that infect human (Lhomme et al., 2020). Human infection with hepatitis E has two different epidemiological patterns. In areas with lower levels of hygiene, HEV1 and HEV2 circulate between humans and through fecal-oral circulation and is usually transmitted by contaminated water. In developed countries, genotypes 3 and 4 are mainly transmitted by animal reservoirs. In addition to acute infection, chronic infection and sometimes cirrhosis in immunocompromised patients have been reported mainly by genotype 3 (Aggarwal, 2011).

Clinical manifestations

The incubation period is about 6 weeks and jaundice develops in 75% of patients. Other symptoms include nausea, fever, muscle aches, vomiting, diarrhea, and abdominal pain. The amount of aminotransferases (ALT) usually varies between 1000 and 3000 international units per liter (Waqar et al., 2020). If pregnant women are infected, the mortality rate, especially in the third trimester, reaches 20–25% (Terrault et al., 2020).

Diagnosis

Diagnosis of infection can be made either indirectly by measuring specific antibodies or directly by tracking the virus genome in the blood or other body fluids. Following a two to six-week incubation period, IgM is produced for a short period (2 weeks before to 5–7 weeks after the onset of symptoms) and is immediately replaced by IgG antibodies. Commercial immunoassay kits and rapid tests based on ORF1/ORF2 peptides or virus antigens can identify antibodies for all four genotypes. There is no genotype-specific serological test for this virus. Cross-reactivity between the virus and other pathogens has not been reported. IgM decreases rapidly after 8 weeks and reaches an undetectable level within 32 weeks. IgG peaks in 4 weeks and stays high for more than a year. IgM indicates an acute illness.

In patients with acute infection, the RNA reaches an undetectable level about 3 weeks after the onset of symptoms, but can be detected in the stool for up to 2 weeks, so a negative molecular test cannot rule out the disease if patients present with late-stage symptoms.

Due to changes in the results of various laboratories, WHO has recently introduced a standard genome based on genotype 3a. If genomic RNA can be traced for more than 3 months, there is a possibility of latency (Pallerla et al., 2020; Aggarwal, 2011).

Interactions between hepatitis E virus and host immune system

Upon hepatocytes HEV-infection, the virus is recognized by the PRRs, including RIG-I, MDA5, TLRs which these receptors activate downstream cascades such as IRF3/7, MAVS and NF- κ B leading to expression of IFNs and ISGs, and other cytokines. These responses are considered as the first line antiviral immunity in the infected cells (Kang and Myoung, 2017).

Besides hepatitis, HEV also can cause a broad spectrum of extra hepatic manifestations in patients such as renal injuries, acute pancreatitis, neurological and placental diseases. Thus, there is a possibility the innate immune sensors in these non-hepatic cells are also able to detect HEV. The studies showed NK cell prevalence is reduced among pregnant women, thus it would reduce their ability to resolve the virus from the liver and may explain why they are more susceptible to severe hepatitis E. The majority of HEV infections are self-limiting and quickly cleared in healthy persons but in immunocompromised patients, HEV infection may progress to persistent hepatitis and liver injury (Lemon and Walker, 2019). Therefore, the host immune defense plays important role in determinant of outcomes of HEV infection. In turn, it has been reported HEV may encode antagonists of immune responses and also through other multiple strategies able to escape and counteract the host immune defense. HEV-ORF1 encodes a polyprotein including functional regions methyltransferase (Met), papain-like cysteine protease (PCP), HVR, macro domain (X), Y, Hel, and the RNA-dependent RNA polymerase (RdRp). Current data suggest that PCP and X proteins inhibit the activation of RIG-I as well as the phosphorylation of IRF3. Inhibition of the expression of ISGs due to inhibiting nuclear translocation and phosphorylation of STAT1 are attributed to the Met and PCP. Also, RdRp has been shown to interact with miRNA for facilitation of virus replication. ORF2 has inhibitory activity of NF- κ B and can impair the host apoptotic response.

HEV ORF3 protein disrupts IFN α -induced STAT1 phosphorylation and down regulate the expression of ISGs, PKR, and MxA (Li et al., 2019). Eventually, interplay between host immunity and the viral proteins indicates the clinical outcome. Nevertheless, in this regard several knowledge gaps remain that need to further investigate.

Introduction

In the late 1970s and early 1980s, an unusual number of young homosexual men, Haitians, heroin addicts, and hemophiliacs in the United States were noted to be dying of normally benign opportunistic infections (Barre-Sinoussi et al., 1983; Gallo et al., 1983). Their symptoms defined a new disease, the acquired immunodeficiency syndrome (AIDS). However, as is now known, AIDS is not limited to these groups but can occur in anyone exposed to the virus. Now approximately 38 million men, women, and children around the world, including 1.2 million in the United States are living with the virus that causes AIDS. While AIDS was initially believed to be a “lifestyle” disease seen primarily in limited populations, it soon became apparent that this was a blood and body fluid borne disease. Most infections in the United States (66% as of 2019, Centers for Disease Control and Prevention, 2019) have been associated with male-male sexual transmission, however, worldwide, approximately 75% of HIV infections are associated with heterosexual transmission. When HIV was identified as the causative agent, it became possible to track the virus and determine the method(s) of transmission (Levy et al., 1984). The virus is transmitted by IV drug abuse, unmonitored blood and organ transplant but mostly unprotected and promiscuous sex and not by any one group of individuals. AIDS was originally a universally fatal diagnosis; however like diabetes, the advent of anti-retroviral drugs has allowed infected persons to live a normal lifespan (reviews on HIV and AIDS: Deeks et al., 2015; Ghosn et al., 2018; Saag, 2021).

Virology

Montagnier and associates in Paris, and Gallo and colleagues in the United States, reported the isolation of the human immunodeficiency virus (HIV-1) from patients with lymphadenopathy and AIDS (Barre-Sinoussi et al., 1983; Gallo et al., 1983). A closely related, less virulent virus, designated HIV-2, was isolated later and is prevalent in West Africa. HIV appears to have been acquired by humans from chimpanzees as early as the 1800s and then spread through Africa and the world by an increasingly mobile population. Although a devastating disease that cannot be completely cured, the development of antiviral drug cocktails (highly active antiretroviral therapy [HAART]) has allowed many HIV patients to resume a normal life.

HIV, like other retroviruses, is an enveloped positive-strand ribonucleic acid (RNA) virus with a unique morphology, encodes an RNA-dependent deoxyribonucleic acid (DNA) polymerase (reverse transcriptase [RT]) and replicates through a DNA intermediate (Rosenthal, 2021). The DNA copy of the viral genome is then integrated into the host chromosome to become a cellular gene.

HIV is a complex retrovirus based on its genome and mode of replication and within the lentivirus class, based on the nature of its disease. Retroviruses are roughly spherical, enveloped, RNA viruses with a diameter of 80–120 nm. The envelope contains the gp120/gp41 viral glycoprotein complex which is acquired by budding from the plasma membrane. The envelope surrounds a capsid that contains two identical copies of the positive-strand RNA genome inside an electron-dense core. The virion also contains 10 to 50 copies of the reverse transcriptase and integrase enzymes and two cellular transfer RNA (tRNAs). These tRNAs are base-paired to each copy of the genome to be used as a primer for the RT. The morphology of the core for HIV resembles a truncated cone which differs from other retroviruses (Fig. 1).

The genome of HIV includes the three major genes similar to all retroviruses which encode polyproteins for Gag (*group-specific antigen*, capsid, matrix, and nucleic acid-binding proteins), Pol (*polymerase*, protease, and integrase), and Env (*envelope*, glycoproteins). These genes encode polyproteins which are subsequently cleaved into functional proteins by cellular and the viral protease. In addition to these genes, HIV also encodes the tat and rev regulatory proteins and the nef, vif, vpr and vpu (HIV-1)/vpx (HIV-2) accessory proteins. The transcripts for these proteins require more complex transcriptional processing (splicing). These proteins promote the processing or virulence of the virus and will be discussed later. At each end of the genome are long terminal repeat (LTR) sequences. The LTR sequences contain promoters, enhancers, and other gene sequences used for binding different cellular transcription factors. Some of the genes are expressed early in the replicative cycle and others, late in the cycle.

Fig. 1 Cross section of human immunodeficiency virus. The enveloped virion contains two identical ribonucleic acid (RNA) strands, RNA polymerase, integrase, and two transfer RNAs (tRNA) base-paired to the genome within the protein core. This is surrounded by proteins and a lipid bilayer. The envelope spikes are the glycoprotein (gp)120 attachment protein and gp41 fusion protein. Replication

HIV infection starts with binding of the viral glycoprotein spikes on the surface of the envelope (trimer of gp120 and gp41 molecules) to the primary receptor, the CD4 protein, and then a second receptor, a 7-transmembrane G-protein-coupled chemokine receptor (Fig. 2) (Rosenthal, 2021). Binding to these receptors determines the tissue tropism and host range of HIV which includes CD4 T cells, myeloid and other cells. The co-receptor used upon initial infection by HIV is CCR5, which is expressed on myeloid and peripheral, activated, central memory, intestinal, and other subsets of CD4 T cells (macrophages, [M]-tropic virus). Later, during chronic infection of a person, the env gene mutates so that the gp120 binds to a different chemokine receptor (CXCR4), which is expressed primarily on T cells (T-tropic virus). Binding to the chemokine receptor activates the cell and brings the viral envelope and cell plasma membrane close together, allowing the gp41 to interact with and promote fusion of the two membranes. Binding to CCR5 and gp41-mediated fusion are both targets for antiviral drugs.

Once the nucleocapsid (genome within the conic protein capsid) is released into the cytoplasm, the early phase of replication begins. As the nucleocapsid traverses the cytoplasm to the nucleus, the RT, encoded by the pol gene, uses the tRNA in the virion as a primer and synthesizes a complementary negative-strand DNA (cDNA). The RT also acts as a ribonuclease H, degrades the RNA genome, and then synthesizes the positive strand of DNA. The RT is a major target for antiviral drugs. During the synthesis of the virion DNA (provirus), sequences from each end of the genome (U3 and U5) are duplicated, thus attaching the LTRs to both ends. This process creates sequences necessary for integration and creates enhancer and promoter sequences within the LTR for regulation of transcription. This creates a DNA copy of the genome which is larger than the original genomic RNA.

RT is very error prone. For example, the error rate for the RT from HIV is one error per 2000 bases, or approximately five errors per genome (HIV, 9000 base pairs). This genetic instability of HIV is responsible for promoting the generation of new strains of virus during a person's disease, a property that switches the tropism of the virus (see glycoprotein above), and can alter the pathogenicity of the virus and promote antiviral resistance or immune escape.

Unlike other retroviruses, the double-stranded cDNA of HIV can enter the nucleus through nuclear pores of resting T cells. However, the genome cannot be utilized until the cell is activated and undergoes division. The genome can remain in the nucleus and cytoplasm in a nonintegrated circular DNA form until the cell is activated. In an activated cell, the cDNA is spliced into the host chromosome with the aid of a virus-encoded, virion-carried enzyme, integrase. Integrase is also a major target for an anti-retroviral drug.

Stimulation of the T cell or macrophages by cytokines, mitogens, in response to other infections, or certain virus infections (e.g. EBV, CMV, HHV6) will generate transcription factors that bind to the LTR to activate the late phase of replication, the transcription

Fig. 2 The life cycle of human immunodeficiency virus (HIV). HIV binds to CD4 and chemokine co-receptors and enters by fusion. The genome is reverse transcribed into deoxyribonucleic acid (DNA) in the cytoplasm, enters the nucleus, and is integrated into the nuclear DNA. Transcription and translation of the genome occur as a cellular gene in a fashion similar to that of human T-cell lymphotropic virus. The virus assembles at the plasma membrane and matures after budding from the cell. *cDNA*, Complementary DNA; *mRNA*, messenger ribonucleic acid. From Rosenthal KS (2021) *Retroviruses*. In Murray PR, Rosenthal KS, Pfaller MA. *Medical Microbiology* 9th edn. pp. 533–549. Elsevier.

of the integrated genome. The viral DNA is transcribed as a cellular gene by the host RNA polymerase II present in activated cells. Transcription of the genome produces a full-length RNA, which like for simple retroviruses is processed to produce several mRNAs that contain the gag, gag-pol, or env gene sequences. The accessory proteins require more complex processing. The full-length transcripts of the genome can also be assembled into new virions.

There are four genotypes of HIV-1, designated M (main), N, O, and P. Most HIV-1 is of the M group, and this group is divided into 11 subtypes, or clades, designated A to K (for HIV-2, A to F). The designations are based on significant differences in the sequence of their env and gag genes and hence the antigenicity and immune recognition of the gp120 and capsid proteins of these viruses. Coinfection of a cell with HIV can allow the two pairs of genomes to recombine and produce hybrids between clades.

Pathogenesis and clinical presentation

As mentioned above, HIV infects cells which express both the CD4 protein and a chemokine receptor resulting in a loss of CD4 positive T cells and monocytes (Fanales-Belasio et al., 2010; Levy, 1993). The loss is most evident in the gut associated lymphoid tissue early in the infection compromising maintenance of barrier and regulatory functions. Chronic stimulation of CD4 and CD8 T cells to HIV and other infections and the HIV induced CD4 T cell death depletes the number of functional cells and causes changes in structure and function to the thymus and lymph nodes. Thus, the infected individual has reduced cell mediated immunity resulting in opportunistic infections.

The original case definition of AIDS, published prior to HIV being identified as the cause, was based on the presence of one or more diseases or conditions indicative of a cell mediated immune deficiency with no known cause for that deficiency. HIV infected individuals are at high risk for viral, fungal, pneumocystis, mycobacterial and parasitic infections (Kerkhoff and Havlir, 2021). CMV retinitis, CNS toxoplasmosis infections, *Pneumocystis jirovecii* and oral candidiasis are common presenting infections. Initially, there was a high incidence of Kaposi's sarcoma seen in late stage AIDS patients, however the incidence of that entity has declined with anti-retroviral treatment. Other blood borne infections also are seen in HIV patients, especially Hepatitis B and C. HIV positive individuals should be screened for each of those entities. In addition to infecting CD4 positive T cells, HIV can infect other CD4 expressing cells, including glial cells in the central nervous system leading to an HIV induced dementia.

The US CDC has staged HIV infection based upon the presence of clinical signs, opportunistic infections and CD4 cell numbers (Fig. 3) (Pahwa et al., 2021). An individual with a negative or indeterminate HIV test who has likely been exposed may be classified as Stage 0. Once an HIV test is positive, an individual may be classified as stage 1. This initial stage of infection may be characterized by a mononucleosis type of syndrome consisting of fatigue, generalized lymphadenopathy and fever. This early retroviral syndrome may last a few weeks. The CD4 count may be normal during this time, however the viral load (see below) will be high. The infection may then enter a quiescent or latent phase. During this period, the virus likely is residing in lymph nodes. The CD4 count may remain stable or slowly decline during this time. In contrast, the viral load may remain at very low levels, or slowly rise during this period. When the CD4 count is below 500 cells/ul, the individual enters Stage 2. This may be an asymptomatic period, or some opportunistic infections, such as CMV, may begin to appear. Stage 3 is entered when the viral load rises, the CD4 count drops below 200 cells/uL and clinically apparent opportunistic infections are present. This is the clinical phase identified as AIDS. In addition to anti-retroviral treatment, individuals in stage 3 may receive anti-pneumocystis prophylaxis and anti-mycobacterial prophylaxis if the CD count drops below 100/ul (Centers for Disease Control, 1981).

Treatment

Initially, an HIV diagnosis was a death sentence. Opportunistic infections might be briefly controlled but there was no effective treatment for the virus. As of this writing (July 2021) there are at least 24 anti-retroviral drugs that may be used in various combinations to treat HIV infected individuals (HIV.gov, 2019; Thompson et al., 2020). Most drugs target the major HIV enzymes, including reverse transcriptase, protease, and integrase. However, there are also cell fusion inhibitors and receptor blockade medications available (Table 1).

The RT inhibitors may be nucleoside (NRTI) or non-nucleoside based (NNRTI). Zidovudine (ZVD), the first anti-retroviral drug used to treat HIV is a nucleoside based anti-RT medication. In an early study, ZVD (known as AZT in its generic form) decreased vertical HIV transmission from 24% to 8%. However, HIV quickly developed mutations rendering it resistant to this medication. This was a harbinger of issues associated with future drugs as the virus is very adept at generating resistant mutations. The biggest advance in anti-retroviral treatment was the use of drug combinations that targeted more than one protein. This highly active anti-retroviral treatment approach, or HAART, initially combined medications that targeted RT and protease (PI). HAART is now referred to as just Anti-Retroviral Treatment (ART). Anti-integrase (INSTI) medications were added and proved effective in keeping viral loads low or even undetectable. Drug combinations also reduce the chance that an individual's virus will develop resistance mutations to multiple drugs simultaneously. If a specific drug combination loses effectiveness, as demonstrated by rising HIV viral loads or decreased CD4 cell counts, laboratories may look for specific resistance mutation in the RT, protease and integrase genes. These methods are detailed below.

While the above-mentioned drug classes work on viral infected cells to inhibit viral replication and assembly, the most recently developed class of anti-retroviral medications prevent viral entry into cells. These medications are not used as front-line treatments but are used when standard ART is ineffective at keeping viral loads low. This class of drugs include a viral gp120-CD4 binding (fostemsavir) inhibitor, a CCR5 antagonist (maraviroc) and monoclonal antibodies targeting the gp120 molecule.

Once a patient is started on anti-retroviral medications, they will be taking those drugs for life. Their medications may need to be changed if their virus develops resistance mutations. The medications are not without side effects, however, and may require an

Fig. 3 Time course and stages of human immunodeficiency virus (HIV). A long clinical latency period follows the initial mononucleosis-like symptoms. Initial infection is with the R5-M-tropic virus, and following mutation, the X4-T-tropic virus. The progressive decrease in the number of CD4 T cells, even during the latency period, allows opportunistic infections to occur. The stages in HIV disease are defined by the CD4 T-cell levels and occurrence of opportunistic diseases. HIV can be detected by the presence of p24, HIV genome or antibodies to the virus. From Rosenthal KS (2021) Retroviruses. In Murray PR, Rosenthal KS, Pfaller MA. *Medical Microbiology* 9th edn. pp. 533–549. Elsevier.

Table 1 Anti retroviral medications.

Nucleoside/Nucleotide Reverse Transcriptase Inhibitors (NRTI)

Abacavir, Didanosine, Emtricitabine, Lamivudine, Stavudine, Tenofovir alafenamide, Tenofovir disoproxil fumarate, Zidovudine

Non-nucleoside Reverse Transcriptase Inhibitors (NNRTI)

Cabotegravir, Delavirdine, Efavirenz, Etravirine, Nevirapine, Risperidine

Protease Inhibitors (PI)

Atazanavir, Darunavir, Fosamprenavir, Indinavir, Lopinavir + Ritonavir, Nelfinavir, Ritonavir, Saquinavir, Tipranavir

Integrase Inhibitors (INSTI)

Biktarvy, Dolutegravir, Elvitegravir, Raltegravir

Fusion Inhibitor

Enfuvirtide

CCR5 antagonist

Maraviroc

alternative ART. Fatigue, gastrointestinal issues, and sleep disorders are known complications. Indinavir, a protease inhibitor, has been associated with kidney stones.

There are two situations where prophylactic anti-retroviral treatment may be given. The first is post exposure prophylaxis. This treatment is used after a single potential exposure to HIV, as in a health care worker receiving a needle stick from an HIV positive patient or a first responder being exposed to blood from an HIV infected individual. The current recommendation is to use a

combination of NNRTI, PI and INSTI medications for 4 weeks post exposure. The medication should be started as soon as at risk exposure is identified, but definitely within 72 h of the exposure (Ford et al., 2018). Rapid HIV testing of the source of the exposure (see below) is routinely used in these situations.

More recently, another form of prophylactic ART, pre-exposure prophylaxis or PrEP, is being used in patients who are not infected with HIV but engage in activities that put them at risk for acquiring HIV. These practices include injection drug use, multiple sexual partners, (heterosexual or homosexual) or a sexual relationship with someone who is known to be HIV infected. Individuals starting PrEP are first confirmed to be HIV negative. They will then take a NRTI based drug combination, Truvada or Descovy, daily. Patients receiving PrEP are tested for HIV at least every 3 months. PrEP has been shown to reduce sexual HIV transmission by over 90% and injection drug use HIV transmission by over 70%. Anecdotally, one of us (TA) has noted a higher-than-expected incidence of syphilis in patients receiving PrEP, possibly due to poorer safe sex practices in those individuals. No formal study has confirmed an association between PrEP and a higher incidence of other sexually transmitted diseases (STDs). However, individuals receiving PrEP are counseled that the treatment is HIV specific and will not protect against syphilis, Chlamydia or other STDs.

Laboratory testing

HIV infection is diagnosed by both antibody and molecular testing (Alexander, 2016; Centers for Disease Control and Prevention and Association of Public Health Laboratories, 2014; Qaseem et al., 2009). The first-generation HIV assays lacked both sensitivity and specificity thus a two-step algorithm was employed. An Enzyme Linked Immunosorbent Assay (ELISA) was used as the first step. Positive specimens were verified by repeat testing followed by a confirming western blot or immunofluorescence assay. These early tests used target antigens obtained from viral culture lysates and detected IgG anti-HIV antibodies. These tests were prone to false positive results and were designed to protect the blood supply, not diagnose an active infection. An infected individual could take 6 weeks or longer to produce a detectable level of antibody, thus a negative result could not be used to rule out an infection. Second and third generation anti-HIV assays used recombinant antigens and detected total antibody (both IgG and IgM) against antigens from both HIV-1 and HIV-2. The third-generation assays reduced the time from infection to diagnosis to 4 weeks. HIV-1 p24 antigen assays, primarily in an ELISA format, were used by blood banks to further reduce the time from infection to detection, as antigenemia precedes detectable levels of antibody by 1–2 weeks. More recently, 4th generation HIV screening assays which detect both antigen and antibody without differentiating them, and 5th generation assays which separately identify p24 antigen and anti-HIV antibody, have been developed (Muthukumar et al., 2015). The current HIV testing algorithm is shown in Fig. 4.

Fig. 4 CDC 4th generation testing algorithm. Centers for Disease Control and Prevention and Association of Public Health Laboratories (2014) Laboratory testing for the diagnosis of HIV infection: updated recommendations. <http://stacks.cdc.gov/view/cdc/23447>, accessed 26 January 2016.

HIV can be transferred from an infected mother to her fetus in utero (Alexander et al., 1999). All serology tests detect an IgG anti-HIV component which can cross the placenta, thus these tests are not useful for identifying HIV infected infants, as maternal antibody would result in a positive result even if the fetus was not infected. Neonatal HIV diagnosis is performed by qualitative PCR testing. The qualitative PCR test is also used to resolve specimens with discrepant results between the first two tests in the current algorithm (Fig. 4). The chances of vertical HIV transmission can be reduced when an infected mother is treated with anti-retroviral therapy.

As mentioned above, HIV infection is a major problem in resource poor areas of the world. These locations may have limited access to facilities that can perform the standard ELISA, chemiluminescent or molecular assays. These areas may use rapid HIV assays, in a card format based on simple ELISA or gold labeled detection methods for HIV screening. These rapid assays are also used in hospitals, emergency rooms and sexually transmitted disease clinics around the world to provide results in as little as 10 min for exposure situations where prophylactic anti-retroviral treatment of an exposed individual may be indicated to prevent a clinical HIV infection. Rapid assays are available for testing serum, whole blood, or oral fluid.

After an individual has been diagnosed with an HIV-1 infection, the amount of virus (viral load) can be monitored with a reverse transcriptase quantitative PCR assay. The immune capabilities of the patient may be followed by determining the % and absolute number of CD4 positive T cells in the peripheral blood. The number of CD4 positive T cells per microliter is used to stage the infection (Fig. 3). Both the viral load and CD4 counts are used to monitor an individual's response to treatment with anti-retroviral drugs.

As mentioned in the treatment section, individuals receiving ART are monitored regularly for viral load levels and CD4 cell counts. The goal of treatment is to reduce the viral load to the lowest or, better still, undetectable levels. Current PCR tests for viral load have a lower limit of detection of 20 HIV copies/ml. This is a vast improvement over the earlier generations of viral load assays that had detection minimums of 75–500 copies/ml. If viral loads do not fall or begin to rise during treatment, it is possible that an individual's virus has developed resistance to one or more of the medications used in their prescribed ART. A laboratory can then subject the individual's virus to an HIV genotype assay which includes genetic sequencing of the RT, protease and integrase genes to determine if there are any mutations known to cause resistance to the medications being used. Alternatively, a more expensive and labor-intensive HIV phenotype assay may be performed. In this procedure, an individual's virus is plated on cells in the presence of specific HIV medications to look for the drug's ability to block the viral replication. There is a combination of the two procedures, an HIV virtual phenotype, which uses the genetic sequence to predict a phenotypic response. In most cases, the HIV genotype assay is sufficient for routine clinical management.

Conclusion

Identifying HIV-1 as the causative agent of AIDS paved the way for developing laboratory testing and treatment modalities. While AIDS remains incurable, viral replication can be controlled by medications and an infected individual's immune response can recover to a point where opportunistic infections may be kept to a minimum. HIV infection remains a serious health problem however, diagnostic, monitoring and treatment regimens continue to improve. One of us (TA) heard Robert A. Good, both a famous and infamous immunologist in the 1960s and 1970s, state at a Medical Laboratory Symposium in Clearwater Florida in 1984 that "AIDS will be a devastating disease but will be the driver of clinical immunology for the foreseeable future." Retrovirology, medical laboratory immunology and clinical infectious disease medicine have certainly been driven greatly by HIV over the past 40 years and the end is not yet in sight.

Glossary

Reoviruses The name “reovirus” comes from taking the letters R, E, and O from “respiratory enteric orphan virus.”

Icosahedral A regular three-dimensional geometric shape consisting of 20 equilateral triangles and 12 vertices.

ISVP Intermediate (or infectious) subviral particle in an intermediate form of reovirus that removed and modified some proteins by proteolytic enzymes, compared to the infectious virion.

Turreted viruses Designating of the presence of spikes or turrets on the surface of the core particles.

Viroplasms Viroplasms are spotted perinuclear structures that may be thought of as “virus factory” or “virus inclusion.” It is an inclusion body in a cell where viral replication and assembly occurs.

Oncolytic viruses (OVs) The cancer-killing viruses that selectively replicate in the tumor cells and newborn mice.

History

The origins of Reoviruses in the case of virus history and evolution are challenging for defining precisely how and when this virus family was first recognized. It seems that they have been evolving for over about 550 million years. The Reoviruses probably originated a long time ago, and named Reoviruses as an acronym for the respiratory enteric orphan virus in 1959, by Sabin A. B (Sabin, 1959). An orphan virus is a virus that is not associated with a disease but may possess pathogenicity (Knipe and Howley, 2013). *Reoviridae* is a family of viruses, which replicate in a wide host range including invertebrates, plants, protozoa, and fungi (Tenorio et al., 2019).

In 1953, Ramos-Alvarez and Sabin isolated the prototype virus for reovirus serotype 1 (reovirus serotype 1 strain Lang, T1L) from the stool of a baby named Lang. In 1955, Ramos-Alvarez and Sabin also isolated the prototypes for reovirus serotype 2 from the stool of a child named Jones who had a summer diarrheal illness (reovirus serotype 2 strain Jones, T2J) and for reovirus serotype 3 from the stool of a child named Dearing (reovirus serotype 3 strain Dearing, T3D). A second prototype for reovirus serotype 3 was isolated from an anal swab from a baby named Abney (reovirus serotype 3 strain Abney, T3A) by L Rosen in 1957 (Fields et al., 1996; Mahy and Regenmortel, 2010).

The reoviruses had particular unique characteristics including:

- I. Their size, which is 73–75 nm for virion and about 64 for infectious subviral particle (ISVP);
- II. The genome consists of 9, 10–12 discontinuous segments of dsRNA, and with the total Mw of the genome is 0.2 to 3.0×10^6 (Urbano and Urbano, 1994).
- III. The entirely cytoplasmic infectious cycle, therefore, exhibits the capacity to produce cytoplasmic inclusions.
- IV. Gene segment exchange (reassortment) occurs among reovirus strains during mixed infections of cultured cells or during coinfection in animal hosts.
- V. The reoviruses display the capacity to hemagglutinate several mammalian erythrocytes (Knipe and Howley, 2013; Winton et al., 1987).

Taxonomy

There are nine taxonomic families of dsRNA viruses. *Reoviridae* is the most important one, which infect vertebrates, including humans. The virus taxonomy (2019 Release) revealed *Riboviria*, *Orthornavirae*, *Duplornaviricota*, *Resentoviricetes*, *Reovirales*, *Reoviridae*, *Spinareovirinae*, *Orthoreovirus*, *Mammalian orthoreovirus*; there are currently 97 species in this family, divided among 15 genera in two subfamilies (Mäntynen et al., 2019; Igori et al., 2020).

The 15 genera of the *Reoviridae* are classified based on ICTV2019 release and are shown in Table 1.

Sedoreovirinae subfamily includes genera containing “smooth” viruses that do not have large surface projections or spikes on their virions or core particles including *Cardoreovirus*, *Mimoreovirus*, *Orbivirus*, *Phytoreovirus*, *Rotavirus*, and *Seadornavirus*.

• Important prototype reoviruses, which marked by *

The *Spinareovirinae* subfamily containing turreted viruses includes genera—that have relatively large spikes or turrets on the icosahedral vertices or core particle—including *Aquareovirus*, *Coltivirus*, *Cypovirus*, *Dinovernavirus*, *Fijivirus*, *Idnoreovirus*, *Mycoreovirus*, *Orthoreovirus*, and *Oryzavirus*. This chapter focuses on the genus *Orthoreovirus*, which contain important human reoviruses. Some member of the *reoviridae* family encodes an additional FAST (fusion-associated small transmembrane) protein responsible for syncytium formation, which shared sequence and structural similarities in avian *reovirus* (ARV) and Nelson Bay *reovirus* (NBV), but is unrelated to the FAST proteins of Baboon *reovirus* (BRV) and Reptilian *reovirus* (RRV). All of these FAST proteins are small, basic, acylated, transmembrane proteins and they induce fusion in transfected cells in the absence of other viral proteins (Boutillier and Duncan, 2011). The only known examples of nonenveloped viruses that induce cell–cell fusion and syncytium formation in the virus-infected cells are members of the family *Reoviridae*. In the case of fusogenic *orthoreoviruses*, syncytium formation promotes a rapid lytic response and release of progeny virions (Salsman et al., 2005). Some of the *orthoreoviruses* are fusogenic and induce syncytia. Members of the genus *Orthoreovirus* have 10 segments of dsRNA contained in two concentric protein capsids (van den Hengel et al., 2013). The genomes of viruses are grouped into three categories corresponding to their size: L [three larges (L1–L3)], M [three mediums (M1–M3)], and S [four smalls (S1–S4)] segments (Kohl et al., 2012). Proteins of viruses in the *Reoviridae* are denoted by the Greek character corresponding to the segment it was translated from (the L segment encodes for λ proteins, the M segment encodes for μ proteins, and the S segment encodes for σ proteins). Most of the genome segments are mono-cistronic, except for S1, which is bi-cistronic or tri-cistronic in some special species (Urbano and Urbano, 1994). Some segments have in-frame initiation codons or additional ORFs (Kohl et al., 2012) and only one strand of each duplex RNA is coding (Knipe and Howley, 2013).

Diverse morphotypes of reovirus particles

Several different morphotypes of reovirus particles are produced during in vitro culturing of reovirus within the cytoplasm of infected cells. These morphotypes of reovirus particles include genome-containing virions (infectious), intermediate subvirion particles (ISVPs), core particles, genome-lacking particles, and undefined particle types (by the capacity to transcribe the genome in vitro “transcriptase” and “replicase” particles) (Jané-Valbuena et al., 1999).

Virions are infectious stable particles in the environment (Antczak and Joklik, 1992) and they sustain infectivity for years when stored below 4 °C (Knipe and Howley, 2013). Infectious subvirion particles (ISVPs) can be modified by proteases. Treatment of virions with chymotrypsin or trypsin in controlled conditions in vitro or during virion disassembly or in the infected intestine condition generates infectious or intermediate subviral particles (ISVPs). These particles lack sigma3 but retain sigma1 and μ 1. The virion-to-ISVP transition can significantly increase the infectivity of these viruses (Snyder et al., 2019). Core particles can be generated in vitro by treating virions with chymotrypsin or trypsin and remove all of the outer-capsid proteins (μ 1, sigma3, and sigma 1) and expose projecting turrets formed by pentamers of lambda2. Purification of reovirus particles from infected cells yields a considerable proportion of particles that lack genomic dsRNA, with lower buoyant density in CsCl gradients (Knipe and Howley, 2013) empty capsids.

Virion and genome characteristics

Members of the *Reoviridae* form nonenveloped virions composed of 1 to 3 concentric capsid layers, which surround 9, 10, 11, or 12 segments of linear dsRNA segments of the viral genome, depending on the genus. The RNA constitutes about 15–20% of the virion dry weight (Benavente and Martínez-Costas, 2007). The positive strands of each duplex have a 5'-terminal type 1 cap structure and negative strands may have phosphorylated 5' termini. Both RNA strands have a 3'-OH group and viral mRNAs lack 3'-polyA tails (King et al., 2011). The viral dsRNA species are present within virus particles in equimolar, representing one copy of each genome segment per virion. Reovirus RNA is usually regarded as noninfectious. However, recent developments involving the introduction of viral mRNAs into susceptible cells have succeeded in recovering fully viable virus particles, thus providing further research opportunities utilizing reverse genetic technologies (Teimoori et al., 2014; King et al., 2011). Mature virions lack a lipid envelope, but in coltiviruses, rotaviruses, and orbiviruses genus, the particles are associated with membrane fractions of the endoplasmic reticulum (ER) during morphogenesis, acquiring an envelope temporarily in infected cells. This is a transitional event in morphogenesis or release of the virus that is subsequently lost or removed. The dsRNA gene segments and enzymes that catalyze RNA transcription, capping, and replication in reoviruses are contained within the inner capsid. RNA-dependent RNA polymerase (as a transcriptase and replicase of the virus), NTPase, helicase, capping, and transmethylese enzymes are, entirely, active in core particles. A unique feature of reovirus replication cycles is the synthesis of viral mRNAs by virally encoded enzymes within the icosahedral particles (Mahy and Regenmortel, 2010). The virus-produced messenger RNA (mRNA) transcripts during multiplication are capped but not polyadenylated. The viral RNA segments are usually mono-cistronic, although some segments have two or three in-frame initiation codons (Knipe and Howley, 2013). Viral factories, and cytoplasmic inclusion bodies, or viroplasms are produced during replication of the virus (Tao et al., 2002).

Reovirus pathogenesis in human

Reoviruses can affect the gastrointestinal system and respiratory tract. Some of these viruses are not associated with any known disease, but some other viruses in the family cause various known diseases. Reovirus infection occurs often in humans, but most cases are mild or subclinical (Mahy and Regenmortel, 2010; Knipe and Howley, 2013). Rotavirus belonging to *Sedoreovirinae* can cause severe diarrhea. They are a major cause of infant disease and death in developing countries. The virus can be readily detected in feces, and may also be recovered from pharyngeal or nasal secretions, urine, cerebrospinal fluid, and blood. Despite the ease of finding reovirus in clinical specimens, their role in human disease or treatment is still ambiguous (Kapikian and Shope, 1996). A variety of symptoms may be associated with *orthoreovirus* infection in human including respiratory illnesses, diarrhea, and intestinal distress in children. In monkeys, *orthoreoviruses* cause hepatitis and extrahepatic biliary atresia. There are several mechanisms of pathogenesis, including the destruction of enterocytes, leading to malabsorption and triggering osmotic diarrhea. A watery characteristic of rotavirus-induced diarrhea is often seen in children prior to the appearance of histologic changes, which is thought to be induced by the action of the rotavirus enterotoxin NSP4 (Nguyen et al., 2004; Razavinikoo et al., 2015). It has been anticipated that the destruction of enterocytes causes a loss of the permeability barrier, resulting in the osmotic pull of fluid from the circulation into the gut. Rotaviruses infect a wide range of mammalian species but restricted in the adults. *Rotavirus A* is responsible for the majority of seasonal endemic diarrheal disease in young children (Nguyen et al., 2004); *Rotavirus B* causes sporadic epidemic outbreaks of gastroenteritis in adults; and *Rotavirus C* causes self-limiting outbreaks of gastroenteritis in young people (Fields et al., 1996).

Transmission and dissemination

Reoviridae family, including rotaviruses, are the most prevalent cause of diarrhea in infants and children (Parashar et al., 1998). Reovirus infections in humans are usually mild or subclinical. Reovirus entry is through respiratory or fecal-oral route with virus replication and pathology in the intestinal epithelium, bile duct epithelium, lung epithelium, leukocytes, and CNS endothelial cells. Reoviruses spread to their host using bloodborne and neural pathways. Rotavirus entry is through the fecal-oral route, with virus replication and pathology in the proximal small intestine, resulting in diarrhea or vomiting (Greenberg and Estes, 2009; Nguyen et al., 2004).

Entry and replication in the host cell

Viruses need host cells for replication. For most viruses, replication, the production of viral proteins and virus assembly, occurs in the cytoplasmic inclusions. In addition, these neoorganelles are also involved in the sequestration of innate immune response proteins (Miller and Krijnse-Locker, 2008). In rotavirus infection, these structures called viroplasms, which are crucial for virus replication. Coexpression of rotavirus NSP5, with NSP2 or VP2, is essential for the formation of this structure. In contrast to rotavirus, reovirus uses ER fragmentation to construct its viral inclusions. Rotavirus uses ER membranes during particle maturation and assembly (Carreño-Torres et al., 2010). *Reoviridae* family use ER membranes during different steps of infection (Miller and Krijnse-Locker, 2008; Knipe and Howley, 2013).

Life cycle

As told before, reovirus genomes consisted of segmented, double-stranded RNA (dsRNA); therefore, replication occurs exclusively in the cytoplasm and the virus encodes several proteins which are needed for replication in the viroplasms (Carreño-Torres et al., 2010). The sigma 1 protein mediates viral binding to cellular receptors containing sialic acid residue and junctional adhesion molecule-A (JAM-A: a member of the immunoglobulin superfamily) and has the capacity to agglutinate erythrocytes of several mammalian species. Following attachment to cell-surface receptors, reovirus is internalized by clathrin- and caveolin-dependent mediated endocytosis (Sturzenbecker et al., 1987; Guglielmi et al., 2006).

The virus is partially uncoated by proteases in the end lysosome, where the capsid is partially digested to allow further cell entry. Cleavage of sigma3 triggers stepwise reovirus disassembly cascade to form distinct ISVP. The host proteins are required for penetration steps. The sigma protein is found distributed in the cytosol, and viral cores are produced by proteolytic removal of outer capsid proteins, and localized in the cytoplasm of infected cells. Following the entering to the cytoplasm, the genome is transcribed and produce (Knipe and Howley, 2013) RNA positive-sense strands. The ^{m7}G-capped viral mRNAs are synthesized early postinfection. In some cell types, such as mouse L929 cells, alongside with the infection progresses, uncapped viral mRNAs are produced. The same positive-sense RNA is used as mRNA templates to synthesize RNA negative-sense strands. In the late phases of the transcription, process is occurred by not capped RNAs. The different amounts of RNAs and translation step are a controlled step. Assembly of viral particles begins in the cytoplasm 6–7 h postinfection. The diverse translational strategy takes place by leaky

scanning, suppression of termination, and ribosomal skipping (Carreño-Torres et al., 2010). Translation of reovirus mRNAs and viral protein synthesis led to the formation of the viral factory. The virus exists in the infected host cell by cell-to-cell movement in occlusion bodies after cell death, and remains infectious until finding another host.

The μ and σ nonstructural proteins of reovirus and $\mu 2$ structural protein are involved in forming and organizing of the inclusion bodies (Becker et al., 2003; Broering et al., 2002). The $\mu 2$ and μ protein interactions are essential for the formation of inclusions and the use of other viral factors for assembly and replication (Parker et al., 2002; Miller et al., 2010). The $\mu 1$, $\mu 2$, $\lambda 3$, σ , and the viral core proteins are involved in virus RNA replication (Broering et al., 2004; Miller et al., 2003). The small part of the virus core ($\mu 2$ protein) is involved in shaping the morphology of inclusions.

The cycle of rotavirus replication occurs entirely in the host cytoplasm. The virus enters the host cell after attachment via the receptor-mediated endocytosis by VP4 and VP7 proteins. The sialic acid-containing receptors are involved in the rotavirus attachments as well. The transcriptionally active viral core particles are released into the cytoplasm and the transcription process begins.

After penetration, positive-sense ssRNAs are synthesized, which are used as a template for synthesizing negative ssRNAs to produce genomic dsRNA and viral proteins (Ebert et al., 2002; Antczak and Joklik, 1992). Inside core particle within inclusions, viral RNAs are synthesized by the reovirus core proteins. The RNA-dependent RNA polymerase (RdRp) is involved in catalytic activity. The RdRp transcribes using negative-strand RNAs as templates for positive-strand RNA synthesis. The viral 2 and VP3 protein are involved in methylation and capping of positive-strand RNAs during releases from the core respectively by reo and rotaviruses (Furuichi et al., 1975). The parental positive-sense RNA strand reanneals with the negative-sense RNA strand to rehabilitate the dsRNA genome.

The $\sigma 1$ protein and its counterpart VP4 in rotavirus as cell attachment proteins are involved in recruiting translation machinery into viral inclusions (Desmet et al., 2014; Knipe and Howley, 2013). The outer capsid proteins increase viral translation by attaching to dsRNA and prevent the binding of protein kinase RNA-activated (PKR) to dsRNA. In uninfected cells, PKR is an IFN-induced enzyme that inhibits the onset of host translation by inhibiting factor 2 subunit α and thus suppressing host protein synthesis (Lemay, 2018).

The virus uses host cell proteins for virus assembly. For example, several chaperone networks including heat shock protein 70 (Hsp70), heat shock protein 90 (Hsp90), and the cytosolic chaperonin T-complex protein 1-ring complex (TRiC) are involved in the aggregation of virus nascent particles within inclusions for assembly.

After assembly and maturation, the mature virions leave virus inclusions (VIs). The viral proteins are associated with the host machinery to boost replication steps inside VIs and prevent an innate immune response. The viral proteins inhibit the activity of the immune system by breaking down interferon regulatory factor 3, which is involved in inducing antiviral defense, within the inclusion (Stanifer et al., 2017).

Replication

Briefly, the entry of reoviruses into the cells commonly results in loss of outer capsid components. Transcriptionally active particles are released into the cell cytoplasm (Fig. 1). The transcription of full-length viroplasmic mRNA species from each dsRNA segment happens within core particles during infection in inclusion bodies, which is localized in the infected cell cytoplasm (Carreño-Torres et al., 2010). This structure appears to be the site of viral mRNA synthesis, genome replication, and particle assembly. The produced mRNAs are used as templates for a minus-strand synthesis and reforming the dsRNA genome segments of a progeny virus particle. The dsRNA genome segments are packaged in exactly equimolar ratios (one copy of each genome segment per particle). The packaging is highly specific, concerning the recognition signals on each mRNA species for recruitment of other segments.

Reassortment in segmented dsRNA viruses

Reassortment is a process of genetic recombination that is restricted to segmented RNA viruses and plays a vital role in the evolution of the viruses with pandemic potential in some viruses. Genome segment reassortment occurred during natural infection or through coculturing of different viruses in the same species, involving the selection and packaging of mRNAs from different parental strains with the same packaging signals (Zafari et al., 2018). The conserved terminal sequences at both ends of RNA segments may be involved as recognition signals for viral transcription, translation, replication, or packaging. The data providing direct evidence of segment reassortment between isolates are only available for viruses in a few genera (Mahy and Regenmortel, 2010; Knipe and Howley, 2013). Closer relations between certain genera have been identified and it has been realized that the nonturreted viruses may represent an ancestral lineage from which the turreted viruses have evolved. For example, comparisons of the polymerase, capping enzyme, and capsid protein sequences, as well as structural analyses of outer capsid proteins, suggest that an evolutionary jump has occurred between the *Seadornaviruses* and *Rotaviruses*, within the *Sedoreovirinae*. This is supposed that gene duplication and rearrangement may occur and cause the changing of the number of genome segments during infection (King et al., 2011).

Fig. 1 Reovirus entry and replication. Reovirus attaches to host glycan coreceptor and JAM-A receptor and enters through receptor-mediated endocytosis. After proteolysis and degradation in early and late endosome, viral core particles are released into the cytoplasm. Positive-sense RNA of reovirus is transcribed and virus proteins are expressed step by step. Virus proteins and genomic materials assemble in viral inclusions and mature reovirus release into the cytoplasm.

Genome segments and protein products

The genome segments and protein products of reovirus and rotavirus are noticeable and visible, almost at a glance in [Table 2](#).

Antigenic properties

The serotype-specific antigen of the *orthoreoviruses* is protein $\sigma 1$, which is recognized by neutralizing antibodies. The MRV $\sigma 1$ and $\sigma 1s$ proteins elicit strain-specific and cross-reactive cytotoxic T-cell activities. The MRV proteins $\lambda 2$ and $\sigma 3$ are species-specific antigens.

Biological properties

Ordinarily, human *orthoreoviruses* do not produce symptoms but may cause upper respiratory tract illness and possibly enteritis in infants and children. Reovirus enters the body as an intact virion. The action of proteases in the intestinal lumen cleaves proteins on the surface of the virion, generating a highly infectious form of the virus the intermediate subviral particle, which interacts with the M cells and is transported into the Peyer's patch where the infection is established. Then the virus may enter the bloodstream or enter nerves for spread to organs such as the brain and spinal cord ([Knipe and Howley, 2013](#)).

Rotaviruses can cultivate in vitro, in permissive epithelial cell lines derived from monkey kidneys. The pretreatment of rotavirus with trypsin enhanced the infection properties. The RF strains of Rotavirus propagated easily in confluent monolayers of fetal rhesus monkey kidney cells (MA-104) and consistently gave high yields of virus titer ([Ahmadi et al., 2016](#)). Viruses within species have the ability to reassort their genome segments, whereas, in different species do not happen under normal conditions.

Distinguishing features of genus *Rotavirus*

Rotaviruses infect only vertebrates and are transmitted by a fecal–oral route. The virus particles have a wheel-like appearance by negative contrast electron microscopy. The triple-layered capsid encloses a genome of 11 linear dsRNA segments and is formed in a

Table 2 Genome segments and protein products of mammalian orthoreovirus and its homologous segment in rotavirus.

Gene segment (Orthoreovirus)	Proteins (Reovirus)	Important function
L1	$\lambda 3$	RNA polymerase (Pol), Interferon antagonist
L2	$\lambda 2$	Guanylyl & Methyl transferase (Cap)
L3	$\lambda 1$	Major inner capsid protein, binds dsRNA and zinc, RNA helicase (Hel)
M1	$\mu 2$	Minor capsid protein, required for inclusion body development, probable RNA polymerase subunit, interferon antagonist, NTPase
M2	$\mu 1$ /Cleaved to form $\mu 1N$ and $\mu 1C$	Important for penetration, influences apoptosis
M3	$\mu NS/\mu NSC$	Binds ssRNAs and cytoskeleton, nucleates viral inclusion bodies, phosphoprotein, μNSC (unknown function) from alternate translation start site
S1	$\sigma 1$ (serotype-specific antigen)	Viral attachment protein, The serotype-specific antigen, cell tropism
S1	$\sigma 1s$	Cell cycle arrest, virus dissemination, elicit strain-specific and cross-reactive cytotoxic T-cell activities
S2	$\sigma 2$	Inner capsid structural protein, weak dsRNA-binding
S3	σNS	ssRNAs-binding, inclusion body development, genome packaging?
S4	$\sigma 3$	Major outer capsid protein, inhibits PKR activation and nuclear and cytoplasmic localization
Genome segment (Rotavirus)	Proteins of Rotavirus	Important function
Segment1	VP1	RNA-dependent RNA polymerase
Segment 2	VP2	Required for encapsidation of VP1 and VP3 and has ssRNA- and dsRNA-binding activity
Segment 3	VP3	Methyl and Guanyl transferase
Segment 4	VP4(88 K) VP8* (28 kD) VP5* (60 kD)	Protease sensitive, neutralizing antigen, viral attachment proteins
Segment 5	NSP1	Interferon antagonist
Segment 6	VP6	Subgroup antigen
Segment 7	NSP3	Binds 3' end of viral mRNAs, cellular eIF4G, Hsp90, inhibits host translation
Segment 8	NSP2	RNA binding, NTPase, forms Viroplasms with VP1 and NSP5
Segment 9	VP7	Glycosylated neutralization antigen, glycoprotein calcium-dependent trimer,
Segment 10	NSP4	Enterotoxin, RER transmembrane glycoprotein, Viroporin, Role in morphogenesis of TLPs
Segment11	NSP5(Product of first ORF)	phosphoprotein, RNA binding, protein kinase, forms viroplasms with NSP2, interacts with VP2 and NSP6
Segment11	NSP6 (Product of 2 _{nd} ORF)	Interacts with NSP5, present in viroplasms and most virus strains, RNA binding

unique morphogenic pathway, which involves the attainment of a transient lipid envelope during budding of immature double-layered particles (DLPs) through the endoplasmic reticulum (ER) and results in the transient acquisition of a lipid envelope and addition of VP4 and VP7 to form the outer virion shell.

The simian rotavirus A/SA11 (SiRV-A/SA11) represents as a prototype of the simian rotaviruses within the genus. The innermost layer of the virion is composed of VP2. The VP2 proteins surround the genomic dsRNAs and two structural proteins, the RdRp and VP1, and the capping enzyme VP3. The assembled genomic dsRNAs, along with the enzymatic complexes and VP2 layer, comprise the rotavirus core. The two outer layers of the rotavirus virion have icosahedral symmetry. The intermediate capsid layer is composed of 260 trimeric VP6. The VP6 layer forms the outer surface of the DLPs. Two proteins (VP4 and VP7) form the outer layer of the rotavirus virion and are required for infectivity. The 260 trimers of VP7 glycoprotein make up the surface of the outermost shell, which is stabilized by Ca^{2+} bound in the inter-subunit interfaces. Although, 60 trimeric VP4 spike proteins project from the same layer as VP7 layer as shown in Fig. 2. The amino-terminal (VP8*) and carboxyl-terminal (VP5*) fragments of VP4 were generated by cleaving by trypsin, and primes virions for infectivity. Virus infectivity is dependent upon the presence of the VP4-VP7 outermost protein layer, the integrity of which requires Ca^{2+} (Blutt et al., 2004). Treatment of virions with Ca^{2+} -chelating agents, such as EGTA or EDTA, destabilizes VP7 trimers, leading to loss of the outer capsid. The infectious virions are resistant to pH ranging from 3 to 9; they are reserved for months at 4 °C in the presence of 1.5 mM $CaCl_2$. Infectivity is also relatively thermostable at 50 °C but can be lost by repeated cycles of freezing and thawing. However, infectivity is lost by treatment with sodium dodecyl sulfate (0.1%), and 95% ethanol, which disrupts the outer protein layer of the virion, representing an effective disinfectant. Double-layered particles (DLPs) are noninfectious, and single-layered rotavirus particles (cores) can be produced by treatment of DLPs with chaotropic agents such as sodium thiocyanate or high concentrations of $CaCl_2$.

Fig. 2 Reovirus (1) and Rotavirus (2) structures and protein contents.

Rotavirus genomic RNA sequences and its related proteins

The rotavirus genome consists of 11 discrete segments of linear dsRNA. When resolved by gel electrophoresis, the segments of *Rotavirus A* strains typically display a 4:2:3:2 distribution pattern. The genome segments are numbered as segment 1 (Seg1) to segment 11 (Seg11) based on increasing electrophoretic mobility. In some *Rotavirus A* isolates, partial duplication of a genome segment was realized during electrophoresis. Rotavirus genomic nucleic acid sequences are A + U rich (58–67%). The segments are completely base-paired, and the plus-strand contains a 5'-terminal cap structure but lacks a polyadenylation signal near its 3' end. In contrast to members of the genus *orthoreovirus*, there is no evidence for the presence of single-stranded oligonucleotides within the virion. Two levels of terminal sequence conservation are evident in *Rotavirus A* isolates. They may be indicative of *cis*-acting signals that are important for controlling transcription, replication, and segment selection for packaging. Detailed genomic information for *Rotavirus B*, *Rotavirus C*, *Rotavirus D*, and novel adult diarrhea rotaviruses (NADRVs) is sparse. However, complete sequence information for all genome segments of rotavirus isolates is available for each species.

The majority of genome segments encode a single protein, but two segments (Seg9 and Seg11) each encode two primary translation products. In the case of Seg9, two initiation codons in the same reading frame may be used, for producing overlapping forms of the VP7 protein. Although, gene Seg 11 contains two out-of-frame ORFs, which results in the translation of two nonstructural proteins containing NSP5 and NSP6. The rotavirus proteins are numbered according to their migration rates upon SDS-PAGE. The six structural proteins have been identified and are given the prefix "VP," whereas nonstructural proteins are given the prefix "NSP." The viral core is composed of three proteins (VP1, VP2, and VP3), that encapsidates the dsRNA genome. The VP1, the largest viral protein (RdRp), is responsible for both transcription and replication. The VP1 is active only in the presence of VP2. The VP3 core protein (the capping enzyme) exhibits guanylyl transferase and methyltransferase activities bind ssRNA. The amount of VP1 and VP3 in the virion is about 12 molecules/particle, but VP2 is the most abundant protein of the viral core, with 120 molecules per virion. The VP2 is required for encapsidation of VP1 and VP3 and has nonspecific ssRNA- and dsRNA-binding activity. By analogy with other reoviruses, it is likely that VP2 determines both the size of the particle and the structural organization of the outer capsid components, the internal enzymatic components, and the RNAs. This important functional load is reflected in the highly conserved nature of VP2.

The intermediate protein layer of the virion is made up of 260 trimers of VP6. The two remaining structural proteins of the virion, VP4 and VP7, of which there are 60 trimers and 260 trimers per virion, respectively, make up the outermost protein layer (Fig. 2). The spike protein VP4 contains a trypsin cleavage site nearly one-third of the way along its length. Cleavage of the protein *in vitro* by trypsin produces two products, VP5* (60 kDa) and VP8* (28 kDa), enhances virus infectivity, and induces conformational changes. The smaller product (VP8*) has hemagglutinin activity and contains a carbohydrate-binding site. The VP7 outer shell glycoprotein is synthesized on the rough ER (RER) and cotranslationally inserted in the ER membrane.

Six nonstructural proteins are encoded by the viral genome. The NSP1 encoded by Seg5 is the most variable protein of rotavirus with 65% sequence diversity observed between strains of *Rotavirus A*. The total length of this genome segment, as well as the size of the ORF, can vary among strains. Although, NSP1 has a conserved cysteine-rich motif near the amino terminus, which is considered as a zinc-binding RING-domain protein. NSP1 has been shown to bind both the 5' end of viral RNA and zinc and has a role in viral pathogenesis as a virulence determining factor. The NSP1 antagonizes the host innate immune response by inducing the degradation of interferon regulatory factors (IRF3, IRF5, and IRF7) required for the expression of type I interferon. It may be done as an E3 ubiquitin ligase. NSP2 self-assembles protein that produces stable octamer, the functional form of the protein. It binds nonspecifically to ssRNA, has NTPase and RTPase activities, and interacts with NSP5 to form viroplasm (Carreño-Torres et al., 2010). The NSP2 has a direct role in virus replication and functions as a molecular motor that plays an important role in viral RNA packaging.

The NSP3 is a multifunctional protein that forms dimers and has several binding partners such as 3' conserved sequence of viral mRNAs and the eukaryotic translation initiation factor eIF4G. Interaction of NSP3 by eIF4G is expected to inhibit host cellular protein synthesis, in that way promoting viral translation (Flint et al., 2015).

A transmembrane protein (NSP4) is synthesized on the RER as a glycosylated protein, had a role in virion maturation, and functions as a receptor for DLPs supports VP4 and VP7 in budding process through the ER membrane. NSP4 also functions as a viral enterotoxin that leads to Ca²⁺ release from internal stores in the ER. The NSP4 cleavage product is secreted from infected cells and binds to integrin receptors and triggering a signaling pathway that activates phospholipase C, leading to Ca²⁺ release. This pathway is distinct from that of intracellularly expressed NSP4, which caused activation of calcium/calmodulin-dependent kinase II (Razavinikoo et al., 2015).

The two lasting nonstructural proteins, NSP5 and NSP6, are encoded by two ORFs in the same viral gene segment. NSP5 has ssRNA- and dsRNA-binding activities and is essential for viroplasm formation and genome replication. Interactions of NSP2 and NSP5 are responsible for viroplasm formation and localization of core proteins. Interactions of NSP2 and NSP5 with core proteins regulate progeny core formation (Knipe and Howley, 2013).

The majority of rotaviruses are predicted to encode a single protein product per segment. It is clear that other rotavirus species have homologs of the proteins characterized by *Rotavirus A* virus. Further insights into the structure and function of viral proteins from species other than *Rotavirus A* look forward to the establishment of suitable permissive cell lines and wait for the production of the non-*Rotavirus A* recombinant proteins.

Genome organization and replication

Generally, the replication cycle of several animal rotaviruses is completed in 12–15 h at 37 °C, in monkey kidneys' continuous cell cultures. The VP4 is the viral attachment protein, and the N-acetyl-sialic acid residues on the cell surface in some animal viruses serve as a receptor behind several integrins and heat shock protein 70 as coreceptors. Recently, the published data mentioned that rotaviruses may enter cells either by receptor-mediated endocytosis or by direct membrane penetration. In both cases, virus entry primes the loss of the outer VP4 and VP7 protein layer and DLP containing transcriptionally active dsRNA was released into the cytoplasm. Within DLP 5'-capped, nonpolyadenylated mRNAs were generated using the full-length minus strand of each genome segment as a template. The regulation of gene expression was done by differences in the level of transcription, which took place from each genome segment. The viral mRNAs support two steps; primarily, the mRNAs act as templates for translation and producing viral proteins, and furthermore, viral mRNAs act as templates for minus-strand synthesis in order to produce dsRNA genome segments during packaging of progeny. Nowadays, evidence showed that the pools of mRNAs that serve as templates for translation (cytosolic +RNA) and replication (viroplasmic +RNA) are distinct (McDonald and Patton, 2011). Virus assembly begins in cytoplasmic inclusions termed viroplasms, which is mediated by NSP2 and NSP5 (Carreño-Torres et al., 2010). During assembly of progeny, the 11 different viral mRNAs interact with one another and with VP1 and VP3, that is followed by association with VP2, for triggering -RNA synthesis and consequently cause the establishment of cores comprising a complete set of 11 dsRNA segments. The most critical Cis-acting replication elements have been identified for minus-strand synthesis. In the intermediate phase of assembly, VP6 is added to core particles, forming DLPs. The next steps in the morphogenesis of progeny virions are unique to rotaviruses and involve recruitment of DLPs to the ER by the NSP4 (Bugarčić and Taylor, 2006). The VP6 protein of *Rotavirus A*, which forms inner capsid proteins, is highly conserved, immunogenic, and contains virus group and subgroup-specific determinants. Although this protein does not induce neutralizing antibodies, it may play a role in the initiation of protective immunity.

The VP4 and VP7 outer capsid proteins elicit neutralizing antibodies. Rotavirus strains were classified based on VP4 and VP7 proteins into P serotypes (VP4 is protease-sensitive) and G serotypes (VP7 is a glycoprotein). Classification of rotaviruses into P (VP4) or G (VP7) serotypes is performed by cross-neutralization assays. So far, 23 G (VP7) genotypes and 32 P (VP4) genotypes have been identified (Matthijnssens et al., 2009). The P genotype is denoted by a number within square brackets, which immediately follows the P serotype.

Therapeutic applications: Oncolytic activity

Tumor relapses after naturally developed viral infections observed in the early last times ago (Donnelly et al., 2013). Subsequent to these former random annotations, the several studies applied viruses as a targeted anticancer therapeutic strategies (Cao et al., 2020). The oncolytic virus (OV) was introduced for this kind of tumor therapy. OV has tumor-selective replication capabilities and can kill tumor cells directly by natural infection and lysis of cancer cells, as well as indirectly by the initiation of systemic antitumor immune responses (Zainutdinov et al., 2019). Reoviruses are isolated from the respiratory and gastrointestinal tract without any known and severe disease (Antczak and Joklik, 1992; Kim et al., 2007). These viruses have served as very productive experimental models for studies of viral pathogenesis (Morin et al., 1996). Most people have been exposed to reovirus by adulthood; however, the infection does not typically produce symptoms. The reoviruses have been demonstrated to have oncolytic (cancer-killing) properties in various cancer cell lines and lyse these cells, encouraging the development of reovirus-based novel therapies for cancer treatment (Soleimanjahi and Habibian, 2020; Lal et al., 2009).

Human reovirus has three prototype strain viruses (Dearing, Lang, Jones) with antitumor properties, but most clinical trials recently focused on the ReoT3D strain (Reolysin). Recently, many researchers evaluated the potential oncolytic activity of Reolysin (reovirus serotype 3-Dearing strain) that is currently used in preclinical and clinical trials for the treatment of various cancers

(Thirukkumaran and Morris, 2009; Min et al., 2009). Also, the second prototype for reovirus serotype 3 was isolated by L Rosen in 1957, from an anal swab reovirus serotype 3 strain Abney, T3A (Fields et al., 1996; Mahy and Regenmortel, 2010), as indicated in Table 3.

Several studies showed significant antitumor effect of oncolytic reovirus against tumor cells. Therapeutic usage of viruses as a cancer treatment opportunity has been increasingly explored over the past years (Thirukkumaran and Morris, 2009; Babaei et al., 2020). The oncolytic viruses (OVs) selectively replicate in the tumor cells and newborn mice are exquisitely sensitive to reovirus infection and have been used as the experimental systems for studies of reovirus pathogenesis. ReoT3D is wild-type reovirus with innate ability to inhibit KRAS signaling pathway in transformed cells (Babaei et al., 2020; Marcato et al., 2005). KRAS mutant cells endorse viral replication by inhibition of PKR and result in the selective replication of reovirus in the KRAS-transformed cells (Fig. 3) (Shmulevitz et al., 2010). Reolysin significantly induces survival rate, apoptosis, and cell cycle arrests and also reduces proliferation, tumor growth, tumor size, and volume in tumor models. The in vitro and in vivo results suggest that reovirus therapy is effective for treatment of tumor cells and it can be considered as a new antitumor option against different tumor cells with KRAS mutations (Babaei et al., 2020).

Oncolytic viruses are thought not only to cause direct destruction of the tumor cells but also to stimulate host antitumor immune system responses.

Immune responses against RV infection

The innate immune response is the first line of host defense against pathogens and is involved in the early detection of viruses in cells; it is followed by activation of adaptive immunity. Innate immune responses depend on the activation of signaling pathways and produce antiviral molecules such as antiviral cytokines like IFNs. Elevated type I interferon increases the expression of

Table 3 The list of species in the genus of mammalian nonfusogenic *Orthoreovirus* with the oncolytic capability.

Mammalian Orthoreovirus	Abbreviation	Reovirus type
Mammalian <i>Orthoreovirus</i> 1	(MRV-1La)	(Reovirus type 1) Lang
Mammalian <i>Orthoreovirus</i> 2	(MRV-2Jo)	(Reovirus type 2) Jones
Mammalian <i>Orthoreovirus</i> 3	(MRV-3De) (T3D)	(Reovirus type 3) Dearing
Mammalian <i>Orthoreovirus</i> 4	(MRV-4Nd)	(Reovirus type 4) Ndelle

Fig. 3 Reovirus oncolysis mechanism. In normal cells after uncoating, PKR recognizes virus dsRNA; then PKR is phosphorylated and activated. Activated PKR phosphorylates eIF2 α , which leads to protein translation block. In Ras-transformed cells, EGFR signaling pathway activates Ras. Ras inhibits PKR, which leads to increase in viral protein's translation, virus replication, and killing of the cells.

interferon-stimulated genes that produce antiviral proteins like 2'-5' oligoadenylate synthetase (OAS) and pattern recognition receptor (PRR) proteins (Li et al., 2015; Silverman, 2007).

The innate immune system immediately detects pathogen-associated molecular patterns (PAMPs), such as genomic DNA, ssRNA, dsRNA, RNA with 5'-triphosphate ends, and viral proteins via PRRs (Parashar et al., 1998; Torres Pedraza et al., 2010; Jensen and Thomsen, 2012). Retinoic acid-inducible gene I (RIG-I)-like receptors (RLRs), Toll-like receptors (TLRs), and NOD-like receptors (NLRs) are three different types of PRRs (Parashar et al., 1998; Medzhitov, 2007) that detect viral particles. Other important roles of TLR and RLRs are the production of type I interferons (IFNs) and proinflammatory cytokines and NLRs involved in the production of mature interleukin-1 β by activating caspase-1 (Pétrilli et al., 2007; Kanneganti et al., 2007).

RIG-I and MDA5 discriminate short and long dsRNAs, respectively, and are major sensors of reovirus infection. DExD/H-box helicase 9 (DHX9), DEAD-Box helicase 1 (DDX1), DDX21, and DHX36 are involved in innate immune response in some cell types like myeloid dendritic cells following (Zhang et al., 2011) reovirus infection. Studies indicated that DHX9 knockdown decreases type I IFN secretion after reovirus infection and it is necessary for IRF-3 and NF κ B activation (Zhang et al., 2011).

Another dsRNA sensor is Toll-Like Receptor 3 (TLR3) (Pandey et al., 2015). TLR3 interaction with its ligand leads to signaling through TRIF and boosts IRF3 and NF- κ B activation. TLR3 does not appear to play an important role in the pathogenesis and clearance of reovirus in the central nervous system, and the absence of TLR3 does not increase viral titers (Pandey et al., 2015; Edelmann et al., 2004).

Interferons are proteins in the cytokine family that have antiviral activity (Knipe and Howley, 2013). The interferon is secreted in the cells due to external stimuli, such as the virus infections, and cells that respond to interferon by establishing an antiviral state (Ja et al., 1987). Interferons are divided into three major groups: type I IFN, type II IFN, and type III IFN.

Type I IFNs bind to a specific cell surface receptor; they are often referred to as viral IFNs and are induced by the virus infection; they include four subtypes: IFN- α (α l leukocyte), IFN- β (fibroblast), IFN- ω (ω II), and IFN- τ (trophoblast).

Type II IFN is mostly referred to as immune IFN and induced by mitogenic or antigenic stimuli. Immune cells such as CD4 Th1 cells, CD8 cytotoxic suppressor cells, and natural killer cells secrete IFN-II. All types of IFNs have antiviral activity and regulate the immune system.

Detection of viral components by RLR and TLR in immune cells leads to the onset of intracellular signaling cascades and secretion of type I IFNs. pDCs are the IFN inducers responsible for producing large amounts of interferon. Dendritic cells (DCs) and fibroblasts produce type 1 interferon.

Type I IFNs adjust to a series of genes expression, including protein kinase R and 2'-5'-oligoadenylate synthase that are involved in reducing viral particles in infected cells, apoptosis, and resistance of uninfected cells to viral infection. Reoviruses are induced and are sensitive to interferon. After recognition of virus ssRNA by PRRs such as RIG-1 like receptor, virus-induced Interferon α/β stimulating intracellular signaling cascade which instates the antiviral mode by expression IFN-stimulated genes (ISGs), transcription factor IRF7 and additional secretion of interferon $\alpha\beta$ (Wilkins and Gale, 2010). Reovirus activates both the RIG-I and MDA5 to induce IFN.

Secreted IFN $\alpha\beta$ binds to the receptor, activates the Jak-STAT signal transduction pathway, and leads to the formation of the heterotrimeric IFN-stimulated gene factor 3 (ISGF3) transcription complex, which leads to the expression of IFN-stimulated genes (ISGs) (Kato et al., 2008).

The amount of interferon released as a result of a reovirus infection depends on the reovirus strain and the type of host cells. For example, viral genes such as M1, L2, and S2 genes are involved in the induction of IFN and sensitivity to IFN $\alpha\beta$. M1, which encodes the reovirus μ 2 protein, is a specific strain interferon suppressor, and even single amino acid changes in this protein can affect host IFN β response.

Interferon secretion is one of the first innate immune system responses to most viruses. The Janus kinases (JAKs), JAK1 and Tyk2, phosphorylate signal transducers and activators of transcription (STATs), STAT1 (STAT1 α and STAT1 β) and STAT2 activated by IFN receptor binding (Nan et al., 2017). STAT1/STAT2 heterodimers with p48 interferon regulatory factor 9 (IRF9) construct the heterotrimeric transcription factor complex IFN-stimulated gene factor 3 (ISGF3) (Veals et al., 1992). ISGF3 bind to ISREs (IFN-stimulated response elements) which is a regulatory DNA sequences and IFN-stimulated genes (ISGs) expression begin such as ISG56 (IFIT1) and transcription factor IRF7 and antiviral mood settled. IRF7 forms homo or heterodimer and increases the transcription of type I IFN genes (Basler et al., 2003). Many viruses such as reovirus suppress the interferon pathway by disrupting the innate immune system. Viruses usually do this in two general ways: first by blocking the host cell sensor machinery or downstream signaling molecules such as IRF3, that inhibit interferon induction and second, viruses suppress IFN signaling by modulation of JAK tyrosine phosphorylation activity, ISG promoter activity interfering, ISGF3 complex degradation (Randall and Goodbourn, 2008).

Viruses have mechanisms to inhibit interferon secretion and ISG protein function such as inactivation of JAKs, degradation or sequestration of STATs, and inhibition of karyopherins required for ISGF3 nuclear translocation. Rotavirus NSP1 protein degrades IRF9 and IRF7 which are necessary for IFN amplification responses (Randall and Goodbourn, 2008).

By suppressing the interferon signaling, the virus can inhibit interferon secretion that is initiated by PRRs and inhibits antiviral IFN-induced gene expression.

IFN type I is able to limit the replication of the virus in cell culture (Randall and Goodbourn, 2008). The activation of the transcription factors Interferon Regulatory Factor 3 (IRF-3) and Nuclear Factor kappa-light-chain-enhancer of activated B cells (NF κ B) (Pandey et al., 2015) begins after antiviral innate immune response stimulation by nucleic acid recognition. IRF-3 activation depends on the cellular double-stranded RNA sensors RIG-I, Mda-5, and IPS-1 (Holm et al., 2007).

Reovirus μ 2 protein inhibits IFN β -induced gene expression. The μ 2 causes nuclear accumulation of IRF9 and suppresses IFN signaling and subversion innate immune response. IRF9 is a transcriptional factor and exists in the cytoplasm that has an essential

role in the signaling pathway leading to expression of ISGs. Reovirus infection stimulates the activation of IRF9 bound to STAT1 and STAT2 and forms ISGF3 complex. ISGF3 complex translocates to the nucleus and binds to ISREs and initiates the transcription of many IFN-stimulated genes (ISGs). Reovirus IFN β modulation is related to the induction of unusual nuclear accumulation of IRF9 by $\mu 2$ protein and inhibition of IFN-stimulated gene (ISG) expression (Holm et al., 2007; Zurney et al., 2009).

One of the most important responses of the innate immune system to reovirus infection in the central nervous system is microglia and astrocyte activation that produces inflammatory cytokines and chemokines including tumor necrosis factor- α (TNF- α) and chemokine (C-X-C motif) ligand 10 (CXCL10), chemokine (C-C motif) ligand 5 (CCL 5) (Kraft et al., 2009). Activated glia and inflammatory mediators are related to a local microenvironment that is deleterious to neuronal survival and endocytic clearance of apoptotic vesicular material. Glial phagocytic activity leads to virus clearance.

Proinflammatory cytokines and chemokines play a role in eliminating virus infection by stimulating inflammation and recruiting innate and adaptive immune cells.

Costimulatory molecules are necessary for T cell activation and lead to acquired immune reactions.

Natural killer cells, mast cells, eosinophils, basophils, and the phagocytic cells including macrophages, neutrophils, and dendritic cells play important role in innate immune responses. Reovirus dsRNA is an innate immune system stimulator that activates dendritic cells (DCs) (Berger et al., 2017).

DCs are one of the most important cells of the immune system that induce inflammatory responses against pathogens. DCs are also involved in adaptive immunity by activating memory T cells, increasing B cell activation, priming naïve T cells, and linking innate and adaptive immunity system by persistent capturing, processing, and presenting antigens to CD4+ and CD8+ T cells. DC and NK cells agitate bystander T cell activation in reaction to TLR agonists via secretion of type 1 IFNs (Kamath et al., 2005). The virus agitates DC to secrete proinflammatory cytokines like IFN- α , TNF- α , and IL-6 and upregulates IFN- γ production and increased NK cytolytic activity. In response to TLR involvement, different subtypes of DC secrete a wide range of inflammatory cytokines such as IFNs type 1, TNF- α , and IL-12, and then activated DC enters into complex interactions with other immune cells including NK cells. NK cells play role in innate and adaptive immunity regulation (Errington et al., 2008; Kalinski et al., 2005).

Adaptive immune response is active after virus antigen presentation by special cells including DCs and virus antigen sensing by PRRs. PRRs define the origin of the antigens distinguished by the antigen receptors expressed on T and B cells, and the type of infection encountered, and instruct lymphocytes to induce the appropriate effector class of the immune response.

Rotavirus induces the two arms of adaptive immune responses. Antibody secretions against rotavirus VP4 and VP7 neutralize viral infection. RV-specific IgA and cytotoxic T cells (CD8+ T cells) involved in the protection and CD4+ T cells mediate the clearance of primary RV infection. Rotavirus induces types I and III interferons and other cytokines, especially Th1 and Th2. T and B cells involve in both clearance of RV and protection from reinfection.

These double-stranded RNA viruses are identified by the innate immune system and activate signaling pathways for inducing an antiviral interferon response. The most important pathways of host immune response to reovirus infection and IFN induction are summarized in Fig. 4.

Fig. 4 Host immune response to reovirus and IFN induction. RIG-1/MDA5 is involved in mitochondrial antiviral signaling and IFN and NF- κ B induction. RIG-1/MDA5 senses virus replication leading to IPS1 recruitment and activation of NF- κ B and IRF3. NF- κ B family are transcription factors involved in host immune response induction and lead to IFN gene transcription. Virus dsRNA is recognized by TLR3 or RIG-1/MDA5. TLR3 activation recruitment TRIF induced Interferon regulatory factor (IRF) family (IRF3 and IRF7) phosphorylation and IFN upregulation.

Conclusion remarks and future perspective

Recently, the researchers improved their knowledge on the reoviruses for understanding and optimizing the complex interactions between OV, tumor cells, and the host immune system. Clarifying of relations between factors such as immune status, tumor types and their mutation profiles, as well as patient responses to virotherapy, will encourage in the development of effective, personalized treatments. In the near future, it seems that using targeted OV therapy in combination with immune-modulating therapies will significantly enhance the contribution of OV to the field of oncology. Nevertheless, many questions remain open to be answered. With a completed or ongoing clinical trial, reovirus therapy is well set to transition from “bench” to “bedside” for cancer therapy.

Introduction

Poxviruses are large, enveloped, double-stranded DNA viruses categorized broadly within the expansive group of Nucleocytoplasmic Large DNA Viruses (NCLDV). Unlike many other eukaryotic DNA viruses that must rely on the nucleus for essential enzymes or metabolites, poxviruses replicate entirely in the cytoplasm of infected cells. Members of the poxvirus family infect a broad range of animal species, from insects to fish to birds to mammals. They pose a significant health threat for animals and humans, most notably exemplified by variola virus (VARV), the causative agent of smallpox.

Poxviridae family taxonomy

The *poxviridae* family is large and encompasses two sub-families: *Entomopoxvirinae* (EPV), which infect insects; and *Chordopoxvirinae* (ChPV), which infect vertebrates. While these two sub-families are highly divergent, they share similar structural and genomic features. Within the EPV sub-family, there are currently four genera recognized by the International Committee on Taxonomy of Viruses (Table 1). Despite an expansion of EPV genomic information in the last 10 years, there have still been relatively few EPV genomes sequenced due to technical difficulties and to date, no GammaEPV genomes have been sequenced. The ChPVs have been far more extensively studied. The number of ChPV genera has been significantly expanded in recent years, reflecting both a boom in the discovery of novel poxviruses and enhanced genomic analysis capabilities. There are now 18 genera within the ChPV sub-family (Table 1), and the genome of at least one member of each genus has been sequenced. ChPV genera can be divided into two clades based on phylogeny (Fig. 1). Clade I represents the evolutionarily more ancient genera including *Orthopoxvirus* and *Avipoxvirus*, whereas clade II represents the more recent genera including *Yatapoxvirus*, *Capripoxvirus*, *Suipoxvirus*, *Cervidpoxvirus* and *Leporipoxvirus*. Salmon gill poxvirus (SGPV) represents the earliest divergence of ChPV, located at the base of the ChPV phylogenetic tree (Gjessing et al., 2015).

Health relevance

The *poxviridae* family has had a powerful impact on both human and animal health. At least five genera (*Centapoxvirus*, *Molluscipoxvirus*, *Orthopoxvirus*, *Parapoxvirus*, and *Yatapoxvirus*) have species which are capable of infecting humans. The most well-known of these are the *Molluscipoxvirus mollusum contagiosum virus* (MOCV), and *Orthopoxviruses* VARV and VACV. *Mollusum contagiosum* is a skin disease commonly affecting children. VARV is the causative agent of smallpox and VACV is the closely related species which was used as the smallpox vaccine. Smallpox was one of the world's most devastating diseases, believed to have caused more deaths than any other infectious disease. The mortality rate for smallpox infections was around 30% and many who survived were left with pockmark scars. The pursuit of a protection from smallpox led to one of the greatest medical innovations in history: vaccination (Barquet and Domingo, 1997). Due to a global vaccination campaign instigated by the World Health

Table 1 The *poxviridae* family.

Genus	Type species	Host
<i>Entomopoxvirinae</i> sub-family		
<i>Alphaentomopoxvirus</i>	<i>Melolontha melolontha entomopoxvirus</i>	Coleoptera (beetles)
<i>Betaentomopoxvirus</i>	<i>Amsacta moorei entomopoxvirus</i>	Lepidoptera and orthoptera (butterflies, moths, grasshoppers)
<i>Deltaentomopoxvirus</i>	<i>Melanoplus sanguinipes entomopoxvirus</i>	Grasshoppers
<i>Gammaentomopoxvirus</i>	<i>Chironomus luridus entomopoxvirus</i>	Diptera (flies and midges)
Unclassified	<i>Diachasmimorpha entomopoxvirus</i>	Wasps
<i>Chordopoxvirinae</i> sub-family		
<i>Avipoxvirus</i>	<i>Fowlpox virus</i>	Birds
<i>Capripoxvirus</i>	<i>Sheeppox virus</i>	Sheep, goats, cattle
<i>Centapoxvirus</i>	<i>Yokapox virus</i>	Humans
<i>Cervidpoxvirus</i>	<i>Mule deerpox virus</i>	Deer and meese
<i>Crocodylidpoxvirus</i>	<i>Nile crocodilepox virus</i>	Crocodiles
<i>Leporipoxvirus</i>	<i>Myxoma virus</i>	Rabbits, hares, and squirrels
<i>Macropopoxvirus</i>	<i>Eastern kangaroopoxvirus</i>	Kangaroos
<i>Molluscipoxvirus</i>	<i>Molluscum contagiosum virus</i>	Humans
<i>Mustelpoxvirus</i>	<i>Sea otterpox virus</i>	Sea otters
<i>Orthopoxvirus</i>	<i>Vaccinia virus</i>	Varied; humans, cows, monkeys, rodents, others
<i>Oryzopoxvirus</i>	<i>Cotia virus</i>	Mice
<i>Parapoxvirus</i>	<i>Orf virus</i>	Sheep, goats, cattle, others
<i>Pteropopoxvirus</i>	<i>Pteropox virus</i>	Bats
<i>Salmonpoxvirus</i>	<i>Salmon gillpox virus</i>	Salmon
<i>Sciuripoxvirus</i>	<i>Squirrelpox virus</i>	Squirrels
<i>Suipoxvirus</i>	<i>Swinepox virus</i>	Pigs
<i>Vespertilionpoxvirus</i>	<i>Eptesipox virus</i>	Bats
<i>Yatapoxvirus</i>	<i>Yaba monkey tumor virus</i>	Monkeys and baboons

Listed are all genera within each of the two *poxviridae* sub-families, type species for each genus, and their host species.

Organization (WHO), smallpox was declared eradicated in 1980 and routine vaccination was ceased. Used as the vaccine, the closely related cowpox (CPXV) and VACV were instrumental for this public health achievement.

Poxvirus infections in animals represent major problems for agricultural industries and wildlife alike. *Avipoxvirus* infections cause major economic losses in egg and poultry industries and have devastated wild bird populations (Smits et al., 2005; Alley et al., 2010). *Capripoxvirus* infections are among the most serious infectious diseases of livestock. *Capripoxviruses* have caused an estimated 30–65% production loss for cattle and sheep farmers in some regions and have proven difficult to control, spreading through the Middle East in the last 10 years (Tuppurainen et al., 2017). *Orthopoxvirus* and *Parapoxvirus* infections in animals are also sources of zoonotic poxvirus infections in humans (Tack and Reynolds, 2011).

Aside from the direct effect on human health, VACV has been used extensively in immunology and virology research, greatly expanding our knowledge of viruses and their interactions with cells and the immune system. In more recent years, VACV and other poxviruses have been modified to be used in applications such as vaccines, gene therapy, and cancer treatment.

Genome

The poxvirus genome consists of linear dsDNA with covalently closed terminal hairpin loops that are incompletely base-paired. These terminal hairpin regions are exceptionally difficult to sequence, but progress has been made thanks to innovations in sequencing technology (Mitsuhashi et al., 2014; Gunther et al., 2017). Between 130–380 kilobase pairs (kbp), poxvirus genomes are among the largest of all viruses. EPV genomes tend to be larger than those of ChPVs (225–380 kbp vs. 170–220 kbp).

Approximately 500 poxvirus genomes have now been sequenced, providing a highly detailed picture of poxvirus genomics and evolution. Genes and their order within the genome can vary significantly across genera, especially within the EPV sub-family. Nonetheless, poxvirus genomes consistently follow a similar arrangement; the genome is organized as a central, conserved region flanked by more variable regions containing inverted terminal repeats. The central conserved region generally encodes genes that are essential for core processes like replication and virion assembly. The flanking regions contain genes dedicated to manipulating the host response to the infection, and consequently are tailored to the host species. Genes that the virus likely acquired from the host through horizontal gene transfer are also located within the flanking regions. Among the over 200 genes encoded by poxviruses, approximately 90 genes are conserved among ChPVs and 49 are conserved between ChPVs and EPVs (Upton et al., 2003). The conventional nomenclature for the prototypical VACV genes consists of a letter from A–O representing fragments generated by restriction endonuclease digestion, followed by a number indicating the open reading frame, and L or R to denote left or right orientation, e.g., B18R. The protein product is called the same name as its gene, but without the L or R, e.g., B18.

Fig. 1 Phylogenetic tree of poxviruses constructed by the maximum-likelihood method from a multiple sequence alignment of concatenated sequences of seven conserved proteins. The tree is midpoint rooted. Scale bar indicates amino acid substitutions per site. Numbers at internal nodes indicate bootstrap support.

Structure

All ChPVs exhibit similar morphology: a brick-shaped or ovoid virion consisting of a central core and one or two lateral bodies enclosed in a lipid envelope. Some poxviruses, particularly parapoxviruses, have a small spiral coil that wraps around the viral particle, resembling a ball of yarn. Virions are large, approximately 350 nm in length and 250 nm in width. As exemplified by the model poxvirus VACV, ChPVs produce two different forms of infectious virions: the mature virus (MV) and enveloped virus (EV). MV contains one envelope decorated with over 20 different viral proteins, most of which are involved in viral attachment and entry. The distribution of the viral proteins on the envelope appears to be highly ordered. For example, microscopy studies of VACV have shown that viral binding and fusion proteins localize to distinct domains on the VACV particle; attachment machinery is located on the sides of the virion and fusion proteins cluster at the tips (Gray et al., 2019). This polarization is critical for proper function. EV is distinguished from MV by the presence of a second outer membrane which contains several unique viral membrane proteins. MV and EV are generated through two different pathways by which the virus may leave host cells, as described below. EVs, while much less abundant than MVs, are the principal mediators of long-distance spread within the host.

While ChPVs are fairly homologous in morphology, EPV core shapes are distinct among the genera. AlphaEPVs are kidney-shaped, BetaEPVs are cylindrical, the singular DeltaEPV is rectangular, and GammaEPVs exhibit the prototypical biconcave dumbbell shape which the rest of the *Poxviridae* family displays.

Replication cycle

Entry

Since VACV is the best-studied poxvirus, we will describe its life cycle as a representative of the family. The replication cycle begins with virus entry, which can be divided into three steps: attachment, fusion, and core entry. There are distinct viral proteins involved in each step. When an MV encounters a host cell, the four attachment proteins on the viral envelope bind to glycosaminoglycans

(GAGs) or laminins on the cell membrane, allowing the virus to attach to the surface of the cell. Note that the EV form of VACV does not have the same attachment proteins on the outer membrane as the MV. Several EV surface proteins have been identified which mediate binding to the cell and trigger disruption of the outer EV membrane. In effect, this releases an MV particle and entry proceeds accordingly.

Depending on the cell type being infected and the virus strain, fusion can be triggered either at the plasma membrane or within endosomes following micropinocytosis. When entering at the plasma membrane, fusion is pH independent. Entry by the endocytic route involves virus-induced cell signaling to trigger engulfment. The lowering of the pH within the endosome as it acidifies is a necessary trigger for fusion of the viral and endosomal membranes. For most viruses, one viral protein is usually involved in membrane fusion. Poxviruses, however, encode an entry-fusion complex (EFC) made up of approximately 11 small proteins which are mostly conserved across genera (Moss, 2012). Nine proteins make up the core complex while two others are peripherally associated. For fusion through both cell surface and endocytic pathways, the viral EFC is required. The EFC fusion machinery normally exists in an inactive state, suppressed by at least two other viral proteins. Low pH or other signals induce the release of these proteins and de-repress the fusion machinery. After the viral and cellular membrane lipids mix and a pore forms, viral cores enter the cytoplasm (Moss, 2016). The cores are then broken down partially through the action of host proteasomes, and the genomes are released.

Transcription and translation

Viral genes are transcribed in three temporally distinct waves: early, intermediate, and late gene transcription. Early genes code for intermediate transcription factors, intermediate genes code for late transcription factors, and late genes produce early transcription factors which are packaged into the virion. Since virions package a comprehensive set of transcription machinery, early gene transcription can begin almost immediately after core entry before uncoating occurs. This is in contrast with other DNA viruses which rely heavily on cellular factors for gene transcription and a key to the ability of poxviruses to forego a nuclear step in its life cycle. The structures of viral DNA-dependent RNA polymerase (vRNAP) complex at a resting state and in active transcription were recently elucidated with cryo-electron microscopy (cryo-EM) (Hillen et al., 2019; Grimm et al., 2019). The core of the vRNAP shares considerable homology with cellular RNAPs, while the periphery displays virus-specific adaptations. Viral mRNAs possess 5' m7G caps and 3' poly(A) tails like eukaryotic mRNAs, but they can have unique features as well. For example, intermediate and late mRNAs have long heterogeneous 3' ends due to a lack of a specific transcription termination signal, resulting in overlapping transcripts and the formation of dsRNA, a pathogen-associated molecular pattern (PAMP) which can be detected by cellular sensors and trigger an immune response.

Many early genes have the critical function of modulating the host antiviral response. Others encode factors needed for genome replication. Uncoating and genome replication is necessary for the genome to be accessible to intermediate transcription factors and the switch to intermediate and late stages of transcription (collectively called post-replicative gene expression) to occur. Post-replicative genes are mainly involved in virion assembly and maturation.

VACV employs a number of mechanisms such as shutting off host protein synthesis or modulating mammalian target of rapamycin (mTOR) activity to co-opt cellular ribosomes and promote viral protein synthesis (Meade et al., 2019a,b). Post-replicative mRNAs have a unique poly(A) leader at the 5' untranslated region (5'-UTR) which facilitate the preferential translation of the viral transcripts (Jha et al., 2017; Dhungel et al., 2017; Rollins et al., 2019; DiGiuseppe et al., 2020).

DNA replication

DNA replication begins very rapidly (~2 h) after entering the cell. A defining characteristic of poxvirus infection is the formation of cytoplasmic inclusions where genome replication and post-replicative gene expression take place. For EPVs, these are called spheroids, and for ChPVs, these are called viral factories. Each factory arises from a single incoming virion. When a cell is infected with more than one virus, viral factories appear to be a physical barrier to recombination (Kieser et al., 2020).

Remarkably self-sufficient, poxviruses encode a complete set of replication machinery, and many poxviruses even possess enzymes for deoxyribonucleotide synthesis. The viral DNA polymerase has 3'-5' proofreading exonuclease activity. Structural studies on the DNA polymerase have produced a highly detailed understanding of the mechanics of this enzyme and how it associates with other factors like the processivity factor (Czarnecki and Traktman, 2017). Despite these structural insights, the mechanism utilized by poxviruses for DNA replication has continuously been debated. It is unclear whether there is a specific origin of replication used by poxviruses since they can catalyze the replication of any circular piece of DNA transfected into an infected cell. However, deep sequencing has identified putative origins of replication in the terminal hairpin region (Senkevich et al., 2015). One model of replication involves self-priming where a nick is made at the terminal hairpin loop, generating an open 3' end. The polymerase extends the open-end, which folds back on itself to create a hairpin. The hairpin serves as a primer for DNA synthesis, which proceeds by strand displacement. Alternatively, there is evidence that replication may occur by the eukaryotic mechanism of leading and lagging strand synthesis. Ultimately, replication produces head-to-tail concatemers which must be cleaved into unit-length genomes by a viral Holliday junction resolvase. Based on the presence of a concatemer resolution motif in the ITR of one EPV genome, it is thought that EPV genome replication is similar to that of ChPVs.

Assembly and egress

Once the genome has been replicated and post-replicative genes are translated, the components of new virions are ready to be assembled. A unique process of membrane biogenesis first generates the highly unusual, open-ended crescent membranes. This process of viral membrane biogenesis is in contrast with most other enveloped viruses which gain their envelope through the process of budding. Though many details are still unclear, crescent formation is thought to be initiated by the insertion of several viral membrane proteins into the ER membrane. One of the membrane proteins promotes membrane curvature and anchors the assembly of a viral protein scaffold on top of the membrane, shaping the membrane into a sphere. Additional regulatory proteins, collectively known as viral membrane assembly proteins (VMAPs), facilitate the rupture of the ER membranes and stabilize the ends. The crescents grow in length while additional viral components like core proteins are directed to the crescents by a complex of seven viral proteins. The genome is funneled in and the spheres close off, forming the immature virion (IV) (Liu et al., 2014). The IV undergoes a morphological transition involving a series of proteolytic reactions, removal of the scaffold, insertion of additional membrane proteins, and structural transformations. This maturation process converts the spherical IV into the brick-shaped intracellular MV, which is fully infectious. MV envelope proteins are not glycosylated, since they do not pass through the ER, again distinguishing poxviruses from most other viruses. Interestingly, SGPV lacks some conserved membrane biogenesis proteins but still displays the visual characteristics of typical poxvirus crescent formation and virion maturation (Gjessing et al., 2015).

The primary mode of virion egress is by passive release when the cell eventually lyses due to infection. A small fraction of MVs, however, migrate via microtubules to the plasma membrane prior to this and exit the cell by exocytosis. Along the way, the MVs are wrapped with two additional membranes from the Golgi or endosomal vesicles, forming the triple-membraned wrapped virus (WV). Several EV-specific membrane proteins traffic to the trans-Golgi where wrapping occurs. There they are incorporated into the virion (Sivan et al., 2016; Monticelli et al., 2020). Since these do pass through the ER, the EV envelope proteins are glycosylated. During the process of exocytosis, the outermost membrane fuses with the plasma membrane, releasing the double-enveloped EV. These can either remain associated with the membrane as cell-associated EVs (CEVs), or induce actin tail formation to be propelled away from the cell surface, enabling cell-to-cell spread (Pickup, 2015).

Superinfection exclusion

Many viruses implement measures to prevent infected cells from being further infected by another virus, a phenomenon known as superinfection exclusion. For VACV, two sets of protein pairs on the plasma membrane of VACV-infected cells effectively prevent superinfection. One pair repels EVs away from cells via actin tails while another heterodimer blocks EFC function of MVs (Turner and Moyer, 2008; Doceul et al., 2010). These fusion blockers have the additional role of inhibiting interactions between viral fusion machinery left on the surfaces of neighboring infected cells, thereby preventing syncytium formation.

Immune response and evasion

The innate immune response is critical for keeping infections under control until adaptive immunity has been ramped up. Complement, natural killer cells, macrophages, dendritic cells, and innate lymphoid cells are all key effectors for early antiviral defense. Programmed cell death is another important line of defense, terminating infected cells before they can produce progeny virions (Veyer et al., 2017; Nailwal and Chan, 2019). As viruses replicating in the cytoplasm, poxviruses are also vulnerable to the cell's arsenal of pattern recognition receptors (PRRs). Cytoplasmic DNA as well as dsRNA by-products from transcription are major PAMPs which activate nucleic acid sensors. Some of the sensors which respond to poxvirus infection include toll-like receptors (TLRs), cyclic GMP-AMP synthase (cGAS), protein kinase R (PKR), melanoma differentiation-associated protein 5 (MDA5), and retinoic acid inducible gene I (RIG-I). The downstream result of activation of these sensors is production of interferon (IFN). IFNs can then act locally on the cell or be secreted to act distantly and stimulate production of cytokines to induce an antiviral state.

Poxviruses have evolved an extensive set of proteins which block activation of the innate immune response or interfere with its downstream effects. Approximately half of the viral coding capacity is dedicated to modulating the immune response. Species within each genus have different sets of immunomodulatory proteins, reflecting the differences in immune systems of the species they infect. Some of the strategies used by the virus to foil the immune response include sequestering viral nucleic acids to avoid detection, deploying direct inhibitors of sensors and key signaling molecules, secreting decoy receptors to intercept pro-inflammatory molecules, and mimicking cellular proteins to act as sinks for their ligands (Smith et al., 2013, 2018; Agrawal et al., 2017; Nichols et al., 2017). Even now, new viral immunomodulatory proteins and modes of inhibiting the immune response continue to be discovered.

While innate immunity is important to provide early control of infections, the adaptive immune response is key for clearance of infection. Based on studies with VACV and ectromelia virus (ECTV, the mousepox virus), infections can be controlled by antibodies as well as cytotoxic T cells (Kennedy et al., 2009). Many of the envelope proteins are prime targets for neutralizing antibodies (Moss, 2011). Immune responses to VACV can be cross-reactive with other orthopoxviruses such as VARV, CPXV, and MPXV due to antigenic similarity among the viruses (Gilchuk et al., 2016). Importantly, poxvirus infections generally elicit long-lasting immunity. For the smallpox vaccine, memory B and T cell responses can be detected several decades after vaccination.

Host range genes

Viruses often require specific cellular receptors to gain access to host cells. Expression of the receptors on host cells consequently dictates cell and host tropism for many viruses. Poxviruses are somewhat unusual in terms of their entry receptor, or rather, lack thereof. No specific entry receptor has been found for poxviruses and it is believed that they use molecules which are present on a wide variety of cells or that there are redundant receptors. Because of this feature, poxviruses are capable of entering nearly all mammalian cell types and their host ranges are largely determined by post-entry factors such as the ability to evade the immune response. These viral factors are collectively known as host range genes. There are more than 10 different classes of host range genes which are variably expressed among different poxvirus species (Werden et al., 2008; Bratke et al., 2013; Oliveira et al., 2017). The absence of certain host range genes is associated with a defect in the virus' ability to infect certain cell types. Host range genes primarily function to block the host antiviral response. This can include inhibition of complement, inflammation, apoptosis, PRRs, or a combination thereof. Several of these genes are functionally redundant. VACV E3L and K3L are two of the most extensively studied host range genes. They prevent host detection of infection by inhibiting PKR. Additionally, VACV K1L and C7L both inhibit cellular antiviral proteins Sterile Alpha Motif Domain-containing 9 (SAMD9) (Sivan et al., 2015; Liu and McFadden, 2015) and SAMD9L (Meng et al., 2018), which together pose a barrier for poxvirus replication. The T2/cytokine response modifier (Crm) gene family is another notable host range gene family. This family acts as cellular Tumor Necrosis Factor Receptor (TNFR) homologs, interfering with TNF signaling and inhibiting apoptosis.

Pathogenesis and clinical diagnosis

EPVs are transmitted by ingestion of spheroids and cause loss of mobility, flaccidity, and whiteness before ultimately killing the insect host after a few weeks. ChPV infections in humans and animals are commonly transmitted by contact with infectious material, often from a lesion on an infected individual. Infections usually remain localized to the skin, though in some cases they can spread, resulting in much more severe disease. MPXV and VARV, which cause more serious illness, are transmitted via the respiratory route as well as by contact with bodily fluids and consequently spread throughout the body. The incubation period for these two viruses is typically 1–2 weeks. In both humans and animals, the hallmark feature of poxvirus infections is a rash or lesions on the skin. Smallpox and MPXV are associated with a number of other symptoms such as fever, headache and body aches, malaise, vomiting, and diarrhea (Fenner and World Health Organization, 1988). *Orthopoxvirus* infections in animals may also manifest as upper respiratory symptoms.

Clinically, diagnosis is made based on the presence of lesions and a history of contact with infected individuals or animals. Diagnosis may then be confirmed by microscopy of material collected from lesions and observation of virions with characteristic poxvirus morphology. Detection of the specific viral genome by PCR is used to distinguish morphologically similar genera.

Treatment

Vaccination is an effective line of defense against poxvirus diseases. Vaccination originated as inoculation of CPXV into the arms of individuals to prevent smallpox, a procedure brought to practice by Edward Jenner. This strategy was based on the observation that dairymaids who contracted CPXV were protected from smallpox (Barquet and Domingo, 1997). As this practice became widespread, VACV replaced CPXV in the vaccine, though it is not clear how or when this happened. For much of the 20th century, the smallpox vaccine consisted of replication-competent VACV, which is antigenically similar enough to VARV that it generates protective immunity against VARV. The VACV vaccine is arguably the most successful vaccine in history, having eradicated a human disease, but it caused significant complications in immunocompromised individuals or those with allergic skin conditions like atopic dermatitis. In these individuals, the infection can become generalized or systemic, causing conditions such as eczema vaccinatum, progressive vaccinia, generalized vaccinia, and postvaccinal encephalitis. Because of this, there have been efforts to attenuate the virus while retaining immunogenicity to make a safer vaccine (Meyer et al., 2020). One such strain, MVA, has been approved for use in several countries. Vaccines also exist for several animal poxviruses, which can help avoid economic losses caused by infection (Bhanuprakash et al., 2012).

Vaccinia immune globulin (VIG), made from blood of vaccinated donors, was an effective treatment from the time when smallpox was endemic (Hopkins and Lane, 2004). Additionally, there is an antiviral drug licensed in the U.S for treating smallpox disease: tecovirimat. A plethora of other drugs which inhibit poxvirus replication at different stages of the life cycle have been identified though few have been tested in vivo as of yet (Delaune and Iseni, 2020).

Poxvirus vectors

Poxviruses have proven useful for the development of vaccines and cancer therapeutics for a number of reasons: (1) their large coding capacity allows for easy insertion of therapeutic genes or vaccine antigens, (2) the fact that they do not enter the nucleus reduces the risk of integration, and (3) they robustly activate the immune system. The broad tissue tropism of some poxviruses

enables delivery of antigens and other therapeutics throughout the body. VACV, *Avipoxviruses*, and *Capripoxviruses* have been engineered as vaccine vectors for infectious diseases of wildlife like rabies, Newcastle disease, and rinderpest virus (Maki et al., 2017; Bournnell et al., 1990; Teffera and Babiuk, 2019). Avian poxviruses, as well as the attenuated MVA VACV strain, are attractive for safe therapeutic use in humans because they do not productively replicate in human cells (Weli and Tryland, 2011). VACV and other poxvirus vectors have shown success as vaccines for numerous pathogens such as influenza, Zika, chikungunya, human immunodeficiency virus (HIV), *Mycobacterium tuberculosis*, and *Plasmodium falciparum* (Altenburg et al., 2014; Prow et al., 2020; Volz and Sutter, 2017). The large coding capacity and ability to simultaneously express more than one foreign antigen allows poxviruses to be developed as multi-valent vaccines (Prow et al., 2018). VACV has also shown promising results as a cancer vaccine and oncolytic virotherapy for a variety of malignancies (Kim and Gulley, 2012; Yang et al., 2018).

Glossary

Cre (Cis-acting replication element) It acts as a template for the viral RNA polymerase 3D^{Pol} for the uridylylation of VPg to form VPg-pU-pU.

IRES (Internal ribosome entry site) IRES is an RNA element that allows initiation of translation in cap-independent manner which helps in the synthesis of proteins.

Polyprotein It is the long protein that forms through the process of translation of open reading frame (ORF) of picornavirus RNA. This polyprotein is processed via proteinases which results in the formation of mature viral proteins.

Positive strand RNA A single molecule of RNA of the PiV helps in the encoding of the functional viral protein through the process of translation in the 5'–3' direction.

Uridylylation The process of the addition of the two uridylyl residues results in the formation of VPg molecule through the PiV RNA dependent RNA polymerase 3D^{Pol} by utilizing a viral RNA template.

VPg It is a virus protein genome linked which acts as a protein primer for the PiV RNA dependent RNA polymerase. This is followed by the uridylylation of VPg-pU-pU which is covalently attached to 5' end RNA of PiV.

Introduction

Picornaviruses (PiVs) are widely distributed across the globe and they are serious threats to human and animal health (i.e., poliomyelitis, encephalitis, meningitis, hepatitis, etc.) PiVs are RNA viruses and differentiated by their biological, biophysical and genetic characteristics (Tuthill et al., 2010a, b). PiVs belong to the family *Picornaviridae* and it consists of 147 species that are grouped into 63 genera (Zell et al., 2017). The major classification of PVs is reported in Table 1. The first virus of this family was identified as foot and mouth diseases virus (FMDV) and the earliest vaccine developed for FMDV and poliovirus (PV) (Loeffler and Frosch, 1898; Enders et al., 1949; Eggers, 1999; Tuthill et al., 2010a, b). PV was the first engineered animal virus in the infection clone and the first virus synthesized outside the cell (Racaniello and Baltimore, 1981a, b; Molla et al., 1991). In 1971, International Committee on Nomenclature of Viruses (ICNV) listed *Picornaviridae* family in their first report (Wildy, 1971). Andre Lwoff (Nobel Laureate, 1965) was elected member of ICNV stated about the name of the family that *Pico* is a prefix of metric system that indicate submultiple unit 10^{-12} and *rna* stands for RNA. Therefore, *picorna* means 10^{-12} ribonucleic acid. It is also stated in the minutes of the subcommittee that the *picorna* refers to *poliomyelitis*, insensitivity to ether, *Coxsackie*, *orphan* and *rhinovirus* (Lwoff and Tournier, 1966; Zell, 2018). The characteristics of *Picornaviridae* family are given in Table 2. The cell entry characteristics for the different PiVs are reported in Table 3. These viruses cause various diseases of the central nervous system (CNS), respiratory system, gastrointestinal tract, heart, liver, pancreas, skin and eye (Grubman and Baxt, 2004; Stanway et al., 2000; Tapparel et al., 2013; Vaughan et al., 2014; Anastasina et al., 2017).

PiVs genome and structure of capsid

PiVs are nonenveloped small RNA viruses (Schwerdt and Schaffer, 1955; Zell et al., 2017; Zell, 2018; Cifuentes and Moratorio, 2019) containing spherical nucleocapsids and they have positive strand polarity in their genomes (Holland et al., 1960; Knipe and Howley, 2013; MacLachlan and Dubovi, 2017). The lengths of the strands are in the range of 6.7–10.1 kilobases for seal picornavirus and goose megavirus, respectively. The 5' end subunit of the RNA virus is covalently bonded with the tyrosine-3 residue of small virus encoded peptide known as 3A or viral peptide genome associated (VPg) (Flanagan et al., 1977; Lee et al., 1977; Ambros and Baltimore, 1978), whereas 3' has a poly tail end (Yogo and Wimmer, 1972; Dorsch-Häsler et al., 1975). Genome codes for a single polyprotein are formed by the process of co- and posttranslationally via virus encoded proteinases to form capsid proteins along with other nonstructural proteins that used in the replication of viral RNA (Maizel Jr, 1963; Jacobson and Baltimore, 1968; Maizel Jr and Summers, 1968; Kiehn and Holland, 1970; Palmenberg, 1990; Strating and van Kuppeveld, 2017). It has been found that dicapiviruses possess a dicistronic genome containing capsid-protein-encoding open reading (ORF) and one ORF coding for nonstructural proteins (Woo et al., 2012a, b).

X-ray diffraction model for PiVs and PV based has been reported, however, a near-atomic three-dimensional structure at a resolution of 2.9 Å of PVs but were not followed till 1985 (Finch and Klug, 1959; Hogle et al., 1985). It has been found that ~200 crystal structures and cryoelectron microscopy structures of PiVs with 7 genera and 17 species were deposited in RCSB Protein

Table 1 Classification of the *Picornaviridae* virus family.

<i>Genus</i>	<i>Species</i>	<i>Genotyping</i>
Enterovirus	Enterovirus-A	Enterovirus-A71
	Enterovirus-B	Coxsackievirus-B3
	Enterovirus-C	Polioviruses
	Enterovirus-D	Enterovirus-D68
	Enterovirus-E	
	Enterovirus-F	
	Enterovirus-G	
	Enterovirus-H	
	Enterovirus-I	
	Enterovirus-J	
	Enterovirus-K	
	Enterovirus-L	
	Rhinovirus-A	Rhinovirus-A2
	Rhinovirus-B	Rhinovirus-B14
	Rhinovirus-C	Rhinovirus-C15
Parechovirus	Parechovirus-A	Human parechovirus 1–16
	Parechovirus-B	
Hepatovirus	Hepatovirus-A	
	Hepatovirus-B	
	Hepatovirus-C	
	Hepatovirus-D	
	Hepatovirus-E	
	Hepatovirus-F	
	Hepatovirus-G	
	Hepatovirus-H	
	Hepatovirus-I	
Aphthovirus	Foot and mouth diseases virus	
	Equine rhinitis A virus	
Cardiovirus	Encephalomyocarditis virus	
	Theilovirus	Saffold virus

Table 2 Characteristics of the family member of *Picornaviridae* (Zell et al., 2017).

<i>Characteristics</i>	<i>Description</i>
Typical member	Poliovirus 1 Mahoney (V01149), species <i>Enterovirus C</i> , genus <i>Enterovirus</i>
Virion	Nonenveloped, 30–32 nm virions comprising 60 protomers
Genome	6.7–10.1 kb of positive sense, nonsegmented RNA with a poly (A) tail
Replication	RNA synthesis occurs in cytoplasmic replication organelles containing nonstructural proteins derived from 2BC-P3 region of the encoded polyprotein. RNA structures at the 5'- and 3'-ends of the genome direct initiation of RNA synthesis and uridylated 3B serves as primer for the synthesis of the RNA strands
Translation	Occurs directly from genomic RNA containing an internal ribosomal entry site (IRES)
Host range	Vertebrates
Taxonomy	Realm <i>Riboviria</i> , kingdom <i>Orthomavirae</i> , phylum <i>Pisuviricota</i> , class <i>Pisoniviricetes</i> , order <i>Picornavirales</i> ; 63 genera containing 147 species

Databank. Icosahedral $T = 1$ /pseudo $T = 3$ the capsid is made up of 60 protomers and each protomer is composed of one copy of the four capsid proteins 1A (VP4), 1B (VP2), 1C (VP3) and 1D (VP1) (Rossmann and Johnson, 1989; Tuthill et al., 2010a, b; Ren et al., 2013).

PiVs proteins nomenclature was proposed with an idealized genome layout L434 diagram (Fig. 1). In the third meeting of the European Study Group of Molecular Biology of Picornaviruses L434 convention agreed and summarized that idealized polyprotein is found to be cleaved into leader protein (L) and polyproteins (P1, P2, P3) in the processing steps. In the next processing steps that lead to the formation of capsid proteins from P1 (i.e., 1Ab, 1C, 1D) precursor, three nonstructural proteins from polyprotein midpiece P2 (i.e., 2A, 2B, 2C) and four nonstructural proteins from P3 (i.e., 3A, 3B, 3C, 3D). 1AB cut leads to the formation of mature capsid proteins 1A and 1B and this occur in some PiVs after incorporation of RNA. The maturation followed by cleavage is RNA catalyzed step which results in the formation of stable infectious virions (Guttmann and Baltimore, 1977; Basavappa et al., 1994; Hindiyeh et al., 1999; Tuthill et al., 2010a, b; Zell, 2018). The place of VP4, VP2, VP3, VP1, VP0 and VPg for 1A, 1B, 1C, 1D, 1AB and 3B may be maintained (Rueckert and Wimmer, 1984a, b; Hughes, 2004; Norder et al., 2011; Zell, 2018). The systematic

Table 3 PVs entry characteristics in cell (Tuthill et al., 2010a, b).

Genus	Species	Features	Receptors	Endocytosis pathway	Initial trigger	Final product	Membrane penetration
Entero	PV	Canyon circling star shaped	PVR (CD155) binds in canyon	Nonclathrin, noncaveolin	Receptor binding	Empty particle	Membrane pore VP4 are formed in channel formation/genome delivery
	HRV	Canyon circling star shaped	LCLr family binds in shallow pits	Clathrin mediated	Low pH	Empty particle	Bafilomycin blocks the entry Size selective pores are formed in endosome membrane
Aphtho	FMDV	Smooth capsid No canyon No pocket	Integrin binds to flexible exposed loop	Clathrin mediated	Low pH	Acid induced dissociation to pentameric subunits	Dissociation occurs with the formation of transient intact empty particle
Cardio	TMEV	Protursion at fivefold Depression at twofold	Sialic acid, Heparan sulfate		Low pH	Acid induced dissociation to pentameric subunits	

**Fig. 1** Schematic diagram of PiVs genome (A) and of dicistronic Dicipivirus genome.

nomenclature shows that the PiVs proteins are in the order polyprotein and the first position is of capsid proteins (VP1–VP4) which refer to their molecular weights in SDS polyacrylamide gel electrophoresis containing VP1 (largest protein) and VP4 (smallest protein) (Fig. 1). The biological and experimental data for newer PiVs are not present but only sequence data are present. Therefore, it has been found that there is variation in the sizes of proteins as compared to that of reference proteins. So the Study Group of PiVs recommended the use of systematic nomenclature (Minor, 1990; Stanway, 1990; Hughes, 2004).

PiVs genome idealized layout is described as VPg + 5'UTR[(L/1A-1B-1C-1D/2A-2B-2C/3A-3B-3C-3D)]3'UTR-poly(A), where, "[]" indicate the open reading frame (ORF) and "/" shows primary cleavage sites leads to the three polypeptides (P1, P2, P3) and "-" is the final processing sites (Agol, 2002; Paul, 2002; Tuthill et al., 2010a, b; Wimmer and Paul, 2010). The multiple copies of a protein if present is numbered as 2A1, 2A2, 2A3, etc., certain proteins are absent in all members of the genus then the respective genome region is indicated by.

"()". PiVs contains orthologous capsid proteins (1B, 1C, 1D), helicase (2C), chymotrypsin-like cysteine proteinase (3C) and RNA dependent RNA polymerase (3D) (Agol, 2002; Paul, 2002; Tuthill et al., 2010a, b; Wimmer and Paul, 2010). Some proteins (i.e., 1A, 2B, 3A, 3B) which are present in PiVs shows divergence and are not similar but, however, their functions are similar. The processed proteins present in PiVs are presented in Table 4.

18 out of 35 PiVs possess highly modified L proteins and they only show their function for genera Aphthovirus, Cardiovirus and Erbovirus. The L-protein of Aphthovirus and Erbovirus is papain-like cysteine proteinase that releases after breaking from C-terminus from nascent polyprotein (Guarne et al., 1998). In addition to this L_{pro} of FMDV is involved in the breakage of eukaryotic elongation factor 4G which leads to the shutoff of the translation process of the host cell (Devaney et al., 1988; Kirchweiger et al., 1994). The L proteins of the cardiovirus inhibit the stress granules and nucleocytoplasmic transport (Bardina et al., 2009; Porter et al., 2010; Borghese and Michiels, 2011). However, the function of L protein is uncertain. There are different types of 2A that exist which release the P1 polypeptide by proteolytic cleavage (2A_{pro} of Enterovirus, Sapelovirus and Rabovirus) or by the translation elongation arrest followed by the re-initiation of translation at the next in-frame codon (2A_{npgp} of Aphthovirus, Aquamavirus, Avihepatovirus, Avisivirus, Cardiovirus, Cosavirus, Erbovirus, Hunnivirus, Kunsagivirus, Limnipivirus, Mischivirus, Mosavirus, Parechovirus B-D, Pasivirus, Potamipivirus, Rosavirus, Senecavirus, Teschovirus and Torchivirus, etc.) (Donnelly et al., 2001).

Table 4 Proteins present in PiVs and their functions (Zell, 2018).

Protein	Type	Function
L, L ^{pro}	Leader protein	Often its function is unknown and L ^{pro} (papain-like proteinase) release itself from polyprotein and targets host proteins
1A (VP4)	Capsid protein	Present inside on the surface of capsid and short like <i>Hepatovirus</i>
1B (VP2)	Capsid protein	It is like jellyroll fold (8 stranded β -barrel) and safe drug binding site
1AB (VP0)	Capsid protein	Precursor of 1A and 1B, remain uncleaved in various genera <i>Ampivirus</i> , <i>Aquamavirus</i> , <i>Avihepatovirus</i> , <i>Avisivirus</i> , <i>Gallivirus</i> , <i>Kobuvirus</i> , <i>Kunsagivirus</i> , <i>Limnipivirus</i> , <i>Megrivirus</i> , <i>Mischivirus</i> , <i>Oscivirus</i> , <i>Parechovirus</i> , <i>Pasivirus</i> , <i>Passerivirus</i> , <i>Potamipivirus</i> , <i>Rosavirus</i> , <i>Sakobuvirus</i> , <i>Salivirus</i> , and <i>Sicinivirus</i> , etc.
1C (VP3)	Capsid protein	It is like jellyroll fold (8 stranded β -barrel) and safe drug binding site
1D (VP1)	Capsid protein	It is like jellyroll fold (8 stranded β -barrel) and safe drug binding site
2A ^{pro}		It is like Chymotrypsin-like cysteine proteinase present in <i>Enterovirus</i> , <i>Sapelovirus</i> and <i>Rabovirus</i> and cleaves the polyprotein at its N-terminus and targets various host proteins
2A ^{NPP}		It initiates cotranslational processing through translation elongation arrest and mediates at the next in-frame codon in member of the genera i.e., <i>Aphthovirus</i> , <i>Aquamavirus</i> , <i>Avihepatovirus</i> , <i>Avisivirus</i> , <i>Cardiovirus</i> , <i>Cosavirus</i> , <i>Erbovirus</i> , <i>Hunnivirus</i> , <i>Kunsagivirus</i> , <i>Limnipivirus</i> , <i>Mischivirus</i> , <i>Mosavirus</i> , <i>Parechovirus B, C, D</i> , <i>Pasivirus</i> , <i>Potamipivirus</i> , <i>Rosavirus</i> , <i>Senecavirus</i> , <i>Teschovirus</i> , and <i>Torchivirus</i> , etc. The length varies from 17 to >150 amino acids and in single genome 6 genes with NPGP present
2A ^{H-box/NC}		2A protein bind with the H-box/NC proteins founds in the H-rev 107 proteins and nonstructural protein of caliciviruses in the members of genera <i>Avihepatovirus</i> , <i>Avisivirus</i> , <i>Gallivirus</i> , <i>Kobuvirus</i> , <i>Megrivirus</i> , <i>Parechovirus</i> , <i>Passerivirus</i> , <i>Potamipivirus</i> , <i>Sakobuvirus</i> , <i>Salivirus</i> , <i>Sicinivirus</i> and <i>Tremovirus</i> and function is unclear
2A ^{NTPase}		2A protein having similarity to AIG1-type guanine-binding domain (P-loop NTPase with GxxGxGKS) and found in the members of genera <i>Avihepatovirus</i> and <i>Avisivirus</i> and function is unclear
2A		2A protein without any similarity with known proteins and the function is unknown. It is found in the genera <i>Ampivirus</i> , <i>Aquamavirus</i> , <i>Dicipivirus</i> , <i>Harkavirus</i> , <i>Hepatovirus</i> , <i>Kunsagivirus</i> , <i>Megrivirus</i> , <i>Oscivirus</i> and <i>Pasivirus</i>
2B		It act as a plasma membrane permeability enhancer (viroporin) and inhibition of host secretory pathways
2C ^{hel}	Helicase protein	P-loop NTPase with GxxGxKS design associated with membrane
2BC	Membrane-anchored protein	It is precursor of 2B and 2C and involved in the formation of replication organelle
3A	Key protein	It is involved in membrane remodeling and all 3A proteins exhibit a C-terminal hydrophobic domain associated membrane
3B (VPg)	Viral peptide	It is associated with tyrosine-3 residue
3C ^{pro}	Chymotrypsin-cysteine proteinase	It is design with GxCG and involved in polyprotein processing, target numerous host proteins, interacts with a cloverleaf-like structure at the 5' end of the positive strand RNA of <i>coxsackievirus</i> and <i>rhinovirus</i>
3D ^{pol}		RNA dependent with modify with KDE, PSG, YGDD and FLKR
3CD ^{pro}		It is precursor of 3C and 3D, PV 3CD _{pro} initiates different processing steps and interacts with cloverleaf-like structure at the end of 5' end of the positive-strand RNA

There is a third type of 2A, 2A^{H-box/NC} which has similarity with the H-rev107 family proteins and the N-terminus of the viral polyprotein (pfam08405) of caliciviruses (Hughes and Stanway, 2000) but its function in the life cycle of the virus is obscure. This 2A^{H-box/NC} is found in the genera *Avihepatovirus*, *Avisivirus*, *Gallivirus*, *Kobuvirus*, *Megrivirus*, *Parechovirus*, *Passerivirus*, *Potamipivirus*, *Sakobuvirus*, *Salivirus*, *Sicinivirus* and *Tremovirus*, etc. *Avihepatovirus* and *Avisivirus* possess the fourth type of 2A and this protein 2ANTPase is similar to the AIG1 (avrRpt2-induced gene 1)-type guanine binding domain found in P-loop NTPases and binds with GxxGxKS (Ding and Zhang, 2007).

PiVs coding region is beside with 5' and 3' nontranslated regions which lead to the formation RNA structures and these RNA structures initiates cap independent translation (Lozano et al., 2016) for Enterovirus synthesis of negative- and positive strand of RNA (Andino et al., 1990). There are five different types of internal ribosome entry sites (IRESs) which engage ribosomes and other host factor to initiate the translation process in PiVs (Jan et al., 2016). Different types of IRES in their respective PiVs genera are given in Table 5. The only member of the genus *Dicipivirus* has two IRESs and unknown IRES for ampiviruses, passeriviruses, potamipiruses and torchiviruses.

Table 5 Type of IRES present in different genera of PiVs.

Type of IRES	Genera of PiVs
I	Enterovirus and Harkavirus
II	Avisivirus, Cardiovirus, Cosavirus, Erbovirus, Gallivirus, Hunnivirus, Mischivirus, Mosavirus, Parechovirus, Rabovirus, Rosavirus, and Sicinivirus
III	Hepatovirus
IV	Aquamavirus, Avihepatovirus, Kunsagivirus, Limnipivirus, Megrivirus, Pasivirus, Sakobuvirus, Sapelovirus, Senecavirus, Teschovirus and Tremovirus
V	Kobuvirus, Oscivirus and Salivirus

Life cycle of PiVs

There is a genetic and phenotypic difference between the family of *Picornaviridae* but all the group members use the same steps for genome replication and production of virus in the host cell favorable environments (Andino et al., 1999; Lin et al., 2009; Jiang et al., 2014). PiV RNA due to positive-sense RNA genome instantly translated into polyprotein when entered into the cell cytoplasm. This does not require the incorporation of viral proteins i.e., polymerase (present inside capsid) (Smyth and Martin, 2002). All PiVs hinder the cap dependent translation of host cell mRNAs and utilized cap dependent translation mechanisms for genome translation by the reduction of the competition of translation factors in between virus and host cell mRNAs. Different steps involved in the life cycle and replication of PiVs are described in the following sections.

Gene expression

The genomes of PiV are encapsulated into icosahedral virion structures which consist of 60 protomers that are formed by the structural proteins in the coding region of P1 (VP1, VP2, VP3, VP4). VP1, VP2 and VP3 (single copy) are arranged into triangular subunit on the surface of the capsid (Bedard and Semler, 2004; Wimmer and Paul, 2010). These subunits arranged themselves on a fivefold symmetrical axis which results in the formation of pentameric protomer. Total 12 of these pentameric subunits are involved in the formation of icosahedrons with two and threefold axes symmetry that is located at the connection points (Agol, 2002; Ehrenfeld et al., 2010). However, VP4 protein is not found on the exterior of the virion and it is located inside of the capsid structure that interacts with the encapsidated RNA genome. The assembling occurs through the incorporation of the RNA genome coincides with the processing of precursor polypeptide, VP0, into VP2 and VP4. The actual phenomena of the maturation of VP0 to form VP2 and VP4 is unknown but whereas the viral proteases 2A, L and 3C/3D were not found to be involved. Therefore, for the maturation of virion the cellular factor is required or the cleavage is affected by RNA/capsid proteins (Agol, 2002; Ehrenfeld et al., 2010).

VP1, VP2 and VP3 (capsid proteins) of *Enteroviruses* and *Rhinoviruses* move from the surface of capsid structure to form mesa at five and threefold axes at the propeller. X-ray crystallographic studies indicate that there is the impression of a cleft in between axes of symmetry which is termed as canyons and these canyons regions were found to be the site of cell receptors for virion binding before entering into the cytoplasm. The cryoelectron micrograph studies have been confirmed this hypothesis that cell receptors are bind to Rhinovirus and Cocksackievirus virion particles (Lawson and Semler, 1990; Belsham, 2009; Jiang et al., 2014). However, in the case of *Cardioviruses* and *Aphthviruses* the canyon regions are not pronounced as compared to that of *Enteroviruses* and *Rhinoviruses*. The neutralization studies investigations show that the virion capsid of the FMDV indicates that in VP1 capsid protein G-H loop is mandatory for the recognition of receptor. The mechanism of entry of virion RNA of the PV is not fully known, however, it may occur through the modification of receptor mediated endocytosis. The acidification of the endosome is not necessary because the release of the viral RNA is not pH dependent (Lawson and Semler, 1990; Belsham, 2009; Jiang et al., 2014).

Translation of RNA genome

The uncoated virus and the released RNA in the cytoplasm of the host cell resulting in the translation of positive strand RNA. The entered viral mRNA is comprised of cis-acting RNA sequence and the structure is different from the mRNA of the host cell (Jackson et al., 1990; Bedard and Semler, 2004; Chase and Semler, 2012). The RNA processing occurs when in the nucleus 7-methyl guanosine cap is attached to the nascent transcript. The transcript is protected from the degradation via recognizing of the cap structure by the complex eIF-4F which serves as a scaffold for the assembling of initiation factors and 40S ribosomal subunit. Genomes of PiVs do not contain anything that is resembled the cap structure and the 5' end of the RNA is covalently linked with the VPg a viral protein and this protein has not been found to play any role in the translation of the polyprotein (Jackson et al., 1990; Bedard and Semler, 2004; Chase and Semler, 2012).

The translation process of PiV positive strand RNA does not obey the conventional scanning model of the ordinary mRNAs (Lin et al., 2009; Daijogo and Semler, 2011). The analysis of the sequence of PiVs and PV shows that 5'-noncoding region (5'-NCR) consists of disparate AUG start codons which is favorable for the initiation for the process of translation (Jackson et al., 1994; Andino et al., 1999). The biochemical analysis of the 5' NCR shows that the viral RNA consists of several secondary structures of RNA which thermodynamic stability hinders the 40S ribosomal subunit to start the codon. Studies indicate that the IRES is used for the translation process of PV RNA genome and all PiVs consist of IRES in 5' NCR (Meerovitch and Sonenberg, 1993; Martínez-Salas, 2008).

Processing of polyprotein

The identification and initiation of the ribosome in PiV IRES lead to the translation of the polyprotein of 250 kDa that is encoded by the single ORF by PiV genomes. Proteinases L or 2A, 3C and 3CD are involved in the proteolytic cleavage of the viral polyprotein (Meerovitch and Sonenberg, 1993; Martínez-Salas, 2008). The processing of viral protein resulting in the formation of precursor molecules P1, P2 and P3 and P1 zone of the polyprotein which is then further processed to yield 3 or 4 proteins. These proteins are the structural components of viral capsid and in *Cardioviruses*, *Aphthoviruses*, *Erboviruses*, *Teschoviruses* and *Kobuviruses* (Kräusslich et al., 1988; Arnold et al., 1987; Leong et al., 2002; Jiang et al., 2014). The P2 precursor (proteolytically processed) is composed of proteins that are mandatory for remodeling of cytoplasmic membranes and vesicles used in the replication of the virus and for the stopping of translation of cell and viral RNA replication. P3 is processed for the production of important proteins for the replication of RNA i.e., RNA dependent RNA polymerase 3D^{Pol} and the viral proteinases (3C, 3D) (Leong et al., 2002; Jiang et al., 2014). These viral proteinases played an important role in the events of viral polyprotein breakage. The synthesis of polyprotein is instantly stopped with the synthesis of the P3 polyprotein on the carboxy terminus of the 3D^{Pol} sequence.

Translation shut off and protein cleavage

The role of 2A (Enteroviruses, Rhinoviruses) and L (Aphthoviruses) in the maturation of viral proteins also possesses a role in the translation activity of the host cell by breaking factors that are involved in the cap dependent translation initiation. These proteinases inhibit the cell protein synthesis by the breakage of eIF-4G component of eIF-4F initiation factor complex which results in the inability of the amino-terminal domain of eIF-4G to recognize and bind with eIF-4E which is linked with 7-methyl cap structure on 5' end of cellular mRNAs. The protein synthesis in Enterovirus and Rhinovirus is enhanced in response to the increased presence of ribosomes that are available for internal ribosome entry. An alternate method used by encephalomyocarditis virus (EMCV) to hinder the translation of host cell by the activation of a cellular translational repressor (4E-BP1). This translational repressor binds cellular eIF-4E and which in turn hinders the host cap-dependent translation.

Replication of viral RNA

PiVs replication utilizes the viral encoded RNA dependent RNA polymerase for the synthesis of RNA from the viral RNA template. The genomic RNA of PiV is released from the capsid into the cytoplasm without replication proteins (Steil and Barton, 2009a, b; Ogram and Flanagan, 2011; Zell et al., 2017; Zell, 2018). The replication of the viral genome initially followed the translation of its coding region for the generation of 3D^{Pol} and other viral replication proteins. Protein VPg as a primer is used by polymerase to induce RNA synthesis by the addition of two uridylyl residues to form VPg-pU-pU. The negative strand RNA is present in the duplex along with the positive sense RNA template. Double stranded RNA is known as replicative form (RF), whereas, negative strand RNA acts as a template for the synthesis of positive strand RNAs. The positive to negative strand ratio of RNA in the infectious cell is 50:1 which suggests that a single negative strand RNA intermediate is used as a template for the formation of multiple positive strand RNAs. Viral positive sense RNA which is newly synthesized is translated to form additional viral proteins that are used as additional template RNA for the production of negative strand RNA or encapsulated inside the virions to infect the host cell (Chase and Semler, 2012; Zell et al., 2017; Zell, 2018).

Along with IRES, PiVs 5' NCRs consist of other stable RNA secondary structural elements which are important for positive- and negative strand RNAs. PiVs such as Aphthoviruses and Cardioviruses contains RNA structure on their 5' terminal and termed as stem loop A that is analogous in function, however, they are not similar in the structural conformation (Ehrenfeld et al., 2010; Langereis et al., 2014; Flather and Semler, 2015). PiVs replication started when they entered the host cell by receptor-mediated endocytosis. The different mechanism has been reported which leads to the formation of endosome which is followed by the alteration in the structure of the capsid and the penetration of viral RNA in the membrane (Tuthill et al., 2010a, b; Siltz et al., 2014). Viral RNA is translated in the cytoplasm which results in the formation of one of the major polyprotein which is then co- and posttranslationally leads to the formation of L protein, capsid proteins (1AB, 1C, 1D), mature nonstructural proteins and some stable intermediates (2BC, 3AB, 3CD) (Fig. 1). RNA dependent RNA polymerase and nonstructural proteins are important for the replication of viral RNA (Baltimore et al., 1963; Tuthill et al., 2010a, b; Siltz et al., 2014). These proteins modify the environment of the cell and initiate the synthesis of negative strand RNA molecules that act as a template for the production of positive strand RNA. Uridylation at cis-replicative elements of VPg occurs and VPg-pU-pU acts as a primer for the synthesis of both positive- and negative-strand RNA (Paul and Wimmer, 2015). The synthesis of viral RNA takes place at a multimeric replication complex using different nonstructural proteins, their precursors and host factors. The components of replication are gathered on the surface of the viral replication organelle (RO). Viral RNA is protected from host nucleases and cytosolic defense mechanisms of the innate immunity by RO (Belov, 2016; Arakawa and Morita, 2019). Membrane associated viral proteins (2B, 2C, 3A) are responsible for the generation of RO which is resulted from the virus induced rearrangement of intracellular membranes. Golgi components and autophagic mechanisms are involved in membrane rearrangement. These ROs are highly dynamic structures that consist of a network of single-membrane vesicles that leads to the formation of double membrane and at later stages lead to the formation of multilamellar agglomerations (Belov, 2016; Arakawa and Morita, 2019). PiVs employ different mechanisms to collect sterols, glycerophospholipids and sphingolipids at ROs. The collection of sterols occurs with the help of 3A protein, phosphatidylinositol, 4-kinases (PI4Ks), phosphatidylinositol 4-phosphate (PI4P) and oxysterol-binding protein (OSBP) as similar for Enteroviruses, Aichivirus, EMCV and Saffold virus. Other strains of PiVs are independent of OSBP (i.e., Hepatitis A virus, human parechovirus, etc.). Virus induced membrane contact sites (VMCSs) result from the endoplasmic reticulum to viral membranes which then in turn regulate the lipid composition of RO membranes which is important for the various functions (Nagy et al., 2016; van der Schaar et al., 2016; Strating and van Kuppeveld, 2017).

Synthesis of positive and negative strand RNA

As stated previously the synthesis of viral RNA occurs by the process of uridylylation of VPg through the viral polymerase 3D^{Pol} and also there is some involvement of other viral proteins (i.e., 3CD) and precursor (i.e., 3AB) (Banerjee and Dasgupta, 2001; Ogram and Flanagan, 2011). The uridylation of VPg leads to the formation of VPg-pU-pU and 3D^{Pol} which forms negative strand RNA which is complementary to the genomic positive sense RNA. Double stranded RNA intermediate (RI) acts as a template for the initiation of the different processes via RNA polymerase for the synthesis of positive strand RNAs (Barton and Flanagan, 1997; Morasco et al., 2003). The negative strand RNA is observed in the infected cell in duplex with positive strand RNA or with various elongating positive strand RNAs present in a double stranded RNA complex which is known as replicative intermediate (RI). The positive strand RNA synthesis is similar to negative strand RNA synthesis which requires uridylylation of VPg and in vitro studies shows that in the synthesis of positive strand RNAs uridylylation of VPg was found to be more effective by utilizing cre RNA hairpin

Fig. 2 The illustration of picornaviruses (PiVs) replication cycle from the invasion of virus in the host cell to the lysis of cell and release of PiVs.

which is the source of template (Steil and Barton, 2009a, b; Flather and Semler, 2015). In the synthesis of positive RNA strand, negative strand template are used to initiate multiple positive strand and cre will act as the site of uridylylation which is necessary for the addition of VPg-pU-pU in positive strand RNAs (Steil and Barton, 2009a, b; Flather and Semler, 2015). The secondary structures in 5' and 3' ends of positive- and negative strand RNAs, respectively, destabilizes the base pairing of RNAs to permit 3D^{Pol} to enter the negative strand RNA template. It has been found that 3D^{Pol} of PV possesses duplex unwinding activity and PV 2C protein consists of NTPases activity and similarity in structure of RNA helicases. 3D^{Pol} and 2C formed a complex which simultaneously helps in the unwinding and chain elongation of the RNA (Herold and Andino, 2000; Teterina et al., 2001; Belsham and Normann, 2008). Cellular proteins initiate the RNA replication and virus translation and they have also been found to interact with the intermediates of negative strand RNA. It has also been found that cellular protein hnRNPC could also interact with the secondary structures of RNA that are formed by the 3' end of PV negative strand RNA and also with 3CD and 2C. It may also be speculated that these hnRNPC complexes and PV replication proteins initiate the positive-strand RNA synthesis (Andino et al., 1999; Lyons et al., 2001; Lin et al., 2009). The formed PiVs particles are released through the process of lysis whereas, for Hepatitis A virus, PV and coxsackievirus B₃ an alternative nonlytic mechanism of viral spread has been reported (Feng et al., 2013; Bird et al., 2014; Robinson et al., 2014; Chen et al., 2015). The schematic illustration of the replication cycle of PiVs is given in Fig. 2.

Factors involved in life cycle

Heat shock proteins

Heat shock proteins (HSP) are of two types HSP 70 and 90 and helps in the folding and unfolding of the proteins. In elevated temperatures and other stress conditions, the expression level is increased. Macejak and Sarnow (1992) explain for the first time that there is the interaction between P1 capsid precursor and HSP 70. Geldanamycin (inhibitor of HSP 90) has been used to evaluate the involvement of cellular chaperone HSP 90 for the inhibition of PV growth in culture cells (Geller et al., 2007a, b). The study shows that HSP 70 delivers protein to the HSP 90 in the partially folded state and it has been suggested that HSP 90 helps in the folding of PVP1 capsid precursor to maintain processing-competent conformation and also helps in the inhibition of proteasomal degradation (Pratt and Toft, 2003; Riggs et al., 2004; Geller et al., 2007a, b). The study has also indicated that HSP 90 played a role in FMDV replication which enhances the production of pentamers from protomer (Newman et al., 2014).

Myristic acid (MA)

It is also known as tetradecanoic acid which is saturated fatty acid and cross-linked with N terminal of the P1 precursor (Chow et al., 1987; Paul et al., 1987; Chow and Moscufo, 1995). Myristic acid (MA) helps in the particle assembly in the earlier and later stage of

the process (Marc et al., 1990; Moscufo et al., 1991) and myristoylation involves two functions in the assembly of particles. In the first step, myristoylated VP0 targets the P1 for the membranous replication complex and whereas in the second step myristic moiety initiates the protomer-protomer interaction of pentamer (Ansardi et al., 1992; Lee and Chow, 1992; Martin-Belmonte et al., 2000). The same functions were found to be pentamer formation of FMDV through myristoylation and during virus maturation VP0 myristoylation occurs in the later stage of assembly (Marc et al., 1990; Moscufo et al., 1991; Ansardi et al., 1992; Goodwin et al., 2009).

Glutathione

Chemically glutathione (GSH) is L-glutamyl-L-cysteinylglycine which is an important reducing agent present in human and animal cells. GSH helps in the maintenance of the redox potential of the cell which is important for immune function. It also possesses an extra role in the process of signal transduction, apoptosis, gene expression and the regulation of protein function (Pompella et al., 2003). The biological activity of the cells is due to the thiol group present in GSH and it exists in reduced (GSH) and oxidized (glutathione disulfide, GSSG) state. The synthesis of GSH involves two steps; the first step involves the linking of glutamate and cysteine which forms dipeptide with the help of the enzyme glutamylcysteine synthase. In the second step, glutathione synthase helps in the catalysis of the addition of glycine in the dipeptide. It has been found that L-buthionine sulfoximine (BSO) is the strong inhibitor of glutamylcysteine synthase and the biosynthesis of GSH (Meister et al., 1979). The inhibition of GSH biosynthesis by BSO hinders the growth of Enteroviruses in morphogenesis and is found to be ineffective on the translation or genome replication (Smith and Dawson, 2006; Ma et al., 2014; Jiang et al., 2014).

Cellular membranes

Positive strand RNA in the virus life cycle in eukaryotic cells is responsible for the rearrangement of the cellular membranes which leads to the formation of specific structures that are associated with replication and encapsidation. Various cellular pathways including secretory pathway, autophagy and lipid biosynthesis were found to be involved in the formation of replication organelles (Kirkegaard and Jackson, 2005; Belov et al., 2008; Hsu et al., 2010; Belov and van Kuppeveld, 2012; Jiang et al., 2014). Tubular structures help in the RNA replication and these replication proteins are present locally and on external surfaces of the membrane facing cytoplasm (Bienz et al., 1992; Belov et al., 2008). It has been found that in early infection the tubular structures possess a single membrane whereas in later stage it converted into double membrane vesicles (Belov et al., 2008; Limpens et al., 2011; Belov and van Kuppeveld, 2012; Jiang et al., 2014). It has been found that the blockage of autophagosome formation resulting in the reduction of RNA replication and whereas acidification is necessary for the final maturation cleavage of the virus (Richards and Jackson, 2012, 2013; Jiang et al., 2014).

Inhibitors of life cycle

Hydantoin

Hydantoin ([5(3,4-dichlorophenyl) methylhydantoin]) (HD) is an organic compound that hinders the life cycle by inhibiting the maturation of 110S intermediate (Vance et al., 1997; Jiang et al., 2014). HD effect is reversible due to 110S particles that are chased in mature virions with the removal of the drug. PiVs are resistant to HD and were isolated with the mutations mapped on the 2C^{ATPase} protein. The presence of HD in cell free translation/RNA replication inhibits the protein processing but no 110S particles were observed (Molla et al., 1991; Verlinden et al., 2000; Jiang et al., 2014).

Guanidine hydrochloride

The viral RNA synthesis and encapsidation are found to be reversibly hinder by guanidine hydrochloride (GnHCl) at a concentration where the cellular macromolecular synthesis would not be affected. It has been found that when GnHCl is added to cells halfway via PiVs infection the RNA is trapped in 80S particles known as guanidons (Baltimore, 1969; Jiang et al., 2014). When a drug is removed 80S particles were found to be decreased with an increase in the concentration of provirions and virions. It has also been found that GnHCl inhibits the ATPase effect of 2C^{ATPase} (Pfister and Wimmer, 1999; Jiang et al., 2014).

L-Buthionine sulfoximide

BSO hinders glutamylcysteine synthase in the biosynthesis of glutathione which is a cellular reducing agent (Meister et al., 1979; Smith and Dawson, 2006; Jiang et al., 2014). GSH inhibition by the treatment of BSO has no notable effect on the RNA replication or protein translation of Enteroviruses. BSO has been found to hinder the assembling of 14S particles that affects the formation of mature virus in infected cells. The pulldown assay of GSH shows that it interacts with 14S, 75S and mature virus particles. In the drug resistant mutants, the mutations in VP1 and VP3 has been found at protomer-protomer interfaces that occur during passaging indicating the role of GSH in the life cycle of Enterovirus which stabilizes the pentamers and virus particles (Meister et al., 1979; Smith and Dawson, 2006; Jiang et al., 2014).

Py-11

Py-11 (2-amino-4,6-dichloropyrimidine) is nucleoside analog potent inhibitor of PiVs life cycle during the process of cleavage of capsid precursor P1 which prevents the formation of pentamers through capsid proteins (La Colla et al., 1981; Jiang et al., 2014).

Geldanamycin

Geldanamycin (GM) is benzoquinone ansamycin antibiotic discovered in *Streptomyces hygroscopicus* that binds with ATP/ADP binding pocket of HSP 90 that hinder its function (Schulte et al., 1998; He et al., 2006). A cellular chaperone (HSP 90) plays an important role in the folding and function of protein kinases, steroid hormone receptors and various cellular proteins that regulates the cell cycle and apoptosis. Geller et al. (2007a, b) found GM which inhibits replication of three different PiVs such as PV, HRV and *Coxsackievirus*. It has been found that GM affects the inhibition of HSP 90 aided folding and viral capsid precursor (P1). This folding is necessary for the processing of P1 through the proteinase 3C^{DPro} (Jiang et al., 2014).

Taxonomy of PiVs

Species of PiVs contain different strains of viruses that are related to each other phylogenetically and their proteins are significantly homologous to each other. The genome maps of these viruses are identical to each other and assume to be compatible in the replication, encapsidation, proteolytic processing and genetic recombination. PiVs species are considerably homologs of the orthologous proteins P1 (divergence <0.66), 2C^{hel}, 3C^{Pro} and 3D^{pol} (divergence <0.64) (Zell et al., 2017; Zell, 2018). Therefore, this confirms the International Code of Virus Classification and Nomenclature (ICVCN) rule that a virus genus contains a group species that share some common characters. There are many PiVs genera which show different distinctive features in their genome maps and indicate the difference in the orthologous proteins (Knowles et al., 2008, 2010). Whereas other remaining proteins (i.e., L, 2A, 2B, 3A, 3B) do not shows any detectable similarities. The *Picornaviridae* Study Group suggests that only orthologous genomes regions of PiVs should be compared. It has been found that the amino acid shows a divergence in a genus in the range of 0.40–0.6 depending on the type of protein (Knowles et al., 2008, 2010). However, in intergenic comparison, the divergence is greater than 0.65. In the species where sequence variation is present VP1 gene region would be used to define genetic types. In the case of *Enterovirus*, it has been found that the genetic types represent antigenic serotypes (Oberste et al., 1999; McIntyre et al., 2013). However, in the case of Enterovirus A, B, C the nucleotide sequence divergence is 0.25 whereas the nucleotide divergence threshold of Rhinovirus A, B, C is 0.12–0.13 (Oberste et al., 1999; McIntyre et al., 2013).

The binomial nomenclature of virus names has been used in which *picornavirus* species is composed of the genus name and adjacent capital letters A, B or C [i.e., Ampivirus (genus) and Ampivirus A (species) (Knowles et al., 2008, 2010)]. There are exceptions Dicipivirus (genus), Cadivirus A (species), Enterovirus (genus) and Enterovirus A to J (species), *Rhinovirus* (genus) *Rhinovirus A* to C and *Megivirus* (genus) and Megivirus A (species). However, Aphthovirus is the only PiVs genus that does not confirm International Committee on Taxonomy of Viruses (ICTV) nomenclature rules because the names of four species were derived from the host species or the diseases caused by them (foot and Mouth diseases virus, Equine rhinitis A virus, Bovine rhinitis A virus, Bovine rhinitis B virus) (Knowles et al., 2008, 2010).

With the invention of next generation sequencing techniques, the novel PiVs have been identified in metagenomics studies as compared to that of classical virus isolation methods and subsequent experimental characterization (Knowles et al., 2008, 2010). The typical composition of PiVs including the presence of IRES, three capsid protein domains with drug-binding sequence, helicase with NTP-binding site (GxxGxGKS/T), VPg with a tyrosine three residue, chymotrypsin like proteinase with GxCGx_{10–18}GxH and RNA dependent RNA polymerase with KDE, PSG, YGDD and FLKR could be reliably used to identify based on their sequences when sometimes some of the features are absent. Also, bioinformation techniques also are helpful to identify the new PiVs and metagenomics studies investigate the intestinal viromes of humans and animals which identify various viruses which are of dietary origin (Zhang et al., 2005; Li et al., 2010a, b, c). The nucleotide composition analysis (NCA) or demonstration of characteristic sequence patterns may be helpful to provide the evidence of the identity of PiVs host, however, NCA provides the distinction between the mammal, insect, plant hosts, discrimination of mammal avian and fish viruses (Lange et al., 2014; Yinda et al., 2017).

The advancement of sequencing techniques increases the identification of PiVs which disclose the unexpected degree of diversity. In 2017 total of 35 genera and 80 species of PiVs has been approved by ICTV and more than 500 types are distinguished genetically or by serological techniques. The different genus of PiVs and their characteristics (i.e., genome length and layout) are reported in Table 6 and the types of PiVs viruses with genus are given in Table 7.

Biochemical and physical properties of PiVs

PiVs genus and its species are quite diverse but these species show some common features of structure and gene expression. Virions are of spheroidal shape particles with 22–30 nm of diameter and there is a lacking of an external lipid coat/envelop (Fig. 3). The diameter of wet or hydrated virus particles was found to be 30 nm through nondestructive methods (Rueckert, 1985). The internal core of the virion is surrounded by a protein shell or capsid and X-ray crystallographic studies confirmed that virions show icosahedral symmetry with the exact position of virus proteins. The composition of capsid protein structure is 60 subunits or protomers arranging themselves around axes of five-, three- and twofold symmetry. PiVs genome is a single strand RNA molecule containing 7400 nucleotides and the size may vary from 7389 to 7441 nucleotides for the different strains of PV and coxsackievirus (Kitamura et al., 1981; Racaniello and Baltimore, 1981a, b; Nomoto et al., 1982; Stanway et al., 1984; Toyoda et al., 1984; La Monica et al., 1986; Iizuka et al., 1987; Jenkins et al., 1987; Lindberg et al., 1987; Pevear et al., 1990). The molecular weight of RNA is 2.58×10^6 Da and all PiVs RNAs contain small basic protein (VPg) which is covalently attached to the 5' end of the genome and polyadenylated tail with a variable length 3' end. The percent weight of virion consists of RNA and protein coat around 30% and

Table 6 Types of PiVs Genus and there characteristics.

<i>Genus</i>	<i>Number of species</i>	<i>Name of species</i>	<i>Genome layout</i>	<i>Genome length</i>
Ampivirus	1	Ampivirus A	VPg + 5'UTRIRES-[1AB-1C-1D/2A-2B-2C/3A-3B-3C-3D]3'UTR-poly(A)	9246 nt (5'-UTR: 970 nt; ORF: 8142 nt; 3'-UTR: 134 nt), length of polyprotein: 2713 aa
Aphthovirus	4	Bovine rhinitis A B, Equine rhinitis A virus, Foot-and-mouth disease virus	VPg + 5'UTRIRES-II[Lpro/1A-1B-1C-1D-2Anpgp/2B-2C/3A-3B-(3B2-3B3)-3C-3D]3'UTR-poly(A)	7250–8203 nt (5'-UTR: up to 1112 nt with poly(C) tract; ORF: 6657–7020 nt; 3'-UTR: 32–110 nt); length of polyprotein: 2218–2339 aa
Aquamavirus	1	Aquamavirus A	VPg + 5'UTRIRES-IV[1AB-1C-1D-2A1npgp/2A2-2B-2C/3A-3B1-3B2-3C-3D]3'UTR-poly(A)	c. 6700 nt (5'-UTR: 506 nt, ORF: 6154 nt, 3'-UTR: 34 nt); length of polyprotein: 2050 aa
Avihepatovirus	1	Vihepatovirus A	VPg + 5'UTRIRES-IV[1AB-1C-1D 2A1npgp/2A2NTPa s e-2A3H-box/NC-2B-2C/3A-3B-3C-3D]3'UTR-poly(A)	Up to 7792 nt (5'-UTR: 625–655 nt, ORF: 6750–6756 nt, 3'-UTR: c. 318 nt); length of polyprotein: 2249–2251 aa
Avisivirus	3	Avisivirus A, B, C	VPg + 5'UTRIRES-II[1AB-1C-1D-(2A 1 n p g p)/2 A 2 n p g p/2 A 3 N T P a s e- 2 A 4 H-box/NC-2B-2C/3A-3B-3C-3D]3'UTR-poly(A)	>7167–7532 nt (5'-UTR: > 457–609; ORF: 6441–6720; 3'-UTR: 194–269 nt); length of polyprotein: 2146–2239 aa
Cardiovirus	3	Cardiovirus A, B, C	VPg + 5'UTRIRES-II[L/1A-1B-1C-1D-2Anpgp/2B-2C/3A-3B-3C-3D]3'UTR-poly(A) Despite a significant similarity, the 2A protein of Cardiovirus C lacks the NPGP motif	c. 7730–8530 nt (5'-UTR: up to 1451 nt with poly(C) tract, ORF: 6879–6924 nt, 3'-UTR: 121–144 nt); length of polyprotein: 2293–2308 aa
Cosavirus	5	Cosavirus A,B,C,D,E,F	VPg + 5'UTRIRES-II[1A-1B-1C-1D-2Anpgp/2B-2C/3A-3B-3C-3D]3'UTR-poly(A)	c. 7632–7802 nt (5'-UTR: up to 1361 nt; ORF: 6366–6402 nt; 3'-UTR: 75–93 nt); length of polyprotein: 2113–2133 aa
Dicipivirus	1	Cadicivirus A	VPg + 5'UTRIRES-II[1A-1B-1C-1D]-IGRIRES[2A-2B-2C/3A-3B-3C-3D]3'UTR-poly(A)	c. 8785 nt (5'-UTR: at least 982 nt; ORF1: 2535 nt; IGR: 588 nt; ORF2: 4221 nt; 3'-UTR: 549 nt); lengths of polyproteins: 845 aa (P1), 1407 aa (P2-P3)
Enterovirus	13	Enterovirus A, B, C, D, E, F, G, H, I, J, Rhinovirus A, B, C	VPg + 5'UTRIRES-II[1A-1B-1C-1D/2Apro-2B-2C/3A-3B-3C-3D]3'UTR-poly(A)	7100–7450 (5'-UTR: 610–822 nt; ORF: 6417–6645 nt; 3'-UTR: 37–99 nt); length of polyprotein: 2138–2214 aa
Erbovirus	1	Erbovirus A	VPg + 5'UTRIRES-II[Lpro/1A-1B-1C-1D-2Anpgp/2B-2C/3A-3B-3C-3D]3'UTR-poly(A)	c. 8828 nt (5'-UTR: up to 905 nt; ORF: 7752–7770 nt; 3'-UTR: 164 nt); length of polyprotein: 2583–2589 aa
Gallivirus	1	Gallivirus A	VPg + 5'UTRIRES-II[L/1AB-1C-1D/2AHbox/NC-2B-2C/3A-3B-3C-3D]3'UTR-poly(A)	c. 8500 nt (5'-UTR: 761 nt; ORF: 7425 nt; 3'-UTR: 310 nt); length of polyprotein: 2474 aa
Harkavirus	1	Harkavirus A	VPg + 5'UTRIRES-II[1A-1B-1C-1D/2A-2B-2C/3A-3B-3C-3D]3'UTR-poly(A)	8003 nt (5'-UTR: 673 nt; ORF: 7263 nt; 3'-UTR: 67 nt); length of polyprotein: 2420 aa
Hepatovirus	9	Hepatovirus A, B,C, D, E, F, G, H, I	VPg + 5'UTRIRES-III[1A-1B-1C-1D-2A/2B-2C/3A-3B-3C-3D]3'UTR-poly(A)	Up to 7810 nt (5'-UTR: c. >225–773 nt; ORF: 6597–6909, nt; 3'-UTR: 35–257 nt); length of polyprotein: 2199–2303
Hunnivirus	1	Hunnivirus A	VPg + 5'UTRIRES-II[L/1A-1B-1C-1D-2Anpgp/2B-2C/3A-3B-3C-3D]3'UTR-poly(A)	7469–7588 nt (5'-UTR: >600–732 nt; ORF: 7432–6822 nt; 3'-UTR: >14,122 nt); length of polyprotein: 2244–2274 aa
Kobuvirus	6	Aichivirus A, B, C, D, E, F	VPg + 5'UTRIRES-V[L/1AB-1C-1D/2AHbox/NC-2B-2C/3A-3B-3C-3D]3'UTR-poly(A)	Up to 8280 nt (5'-UTR: up to 744 nt; ORF: 7299–7467 nt; 3'-UTR: 136–240 nt); length of polyprotein: 2432–2488 aa
Kunsagivirus	1	Kunsagivirus A	VPg + 5'UTRIRES-IV[1AB-1C-1D-2A1npgp/2A2-2B-2C/3A-3B-3C-3D]3'UTR-poly(A)	c. 7092–7429 nt (5'-UTR: 393–532 nt; ORF: 6639–6729 nt; 3'-UTR: 25–177 nt); length of polyprotein: 2213–2248 aa
Limnipivirus	3	Limnipivirus A, B, C	VPg + 5'UTRIRES-IV[1AB-1C-1D-2A1npgp/2A2npgp/-2B-2C/3A-3B-3C-3D]3'UTR-poly(A)	c. 7700–8050 nt (5'-UTR: > 501–712 nt; ORF: 6810–7011 nt; 3'-UTR: 312363 nt); length of polyprotein: 2270–2337 aa
Megrivirus	1	Melegrivirus A	VPg + 5'UTRIRES-IV[(L)1AB-1C-1D/(2A0-2A1-2A2-)2A3H-box/NC-2B-2C/3A-3B-3C-3D]3'UTR-poly(A)	9040–9840 nt (5'-UTR: >461–663 nt; ORF: 8235–8520 nt; 3'-UTR: >175–669 nt); length of polyprotein: 2745–2886 aa
Mischivirus	3	Mischivirus A,B,C	VPg + 5'UTRIRES-II[L/1AB-1C-1D-2Anpgp/2B-2C/3A-3B-3C-3D]3'UTR-poly(A)	c. 8457 nt (5'-UTR: 1407 nt; ORF: 6846 nt; 3'-UTR: 204 nt); length of polyprotein: 2282 aa
Mosavirus	1	Mosavirus A	VPg + 5'UTRIRES-II[L/1A-1B-1C-1D-2Anpgp/2B-2C/3A-3B1-3B2-3C-3D]3'UTR-poly(A)	c. 8385 nt (5'-UTR: >646 nt; ORF: 7653 nt; 3' UTR: 86 nt); length of polyprotein: 2551 aa
Oscivirus	1	Oscivirus A		

Table 6 (Continued)

Genus	Number of species	Name of species	Genome layout	Genome length
Parechovirus	4	Parechovirus A,B,C,D	VPg + 5'UTRIRES-V[L1AB-1C-1D/2A-2B-2C/3A-3B-3C-3D]3'UTR-poly(A)	c. 7640–7678 nt (5'-UTR: 636–646 nt; ORF: 6765–6774 nt; 3' UTR: 238–256 nt); length of polyprotein: 2255–2258 aa
Pasivirus	1	Pasivirus A	VPg + 5'UTRIRES-II[L1AB-1C-1D-(2Anpgp)/2AH-box/NC-2B-2C/3A-3B-3C-3D]3'UTR-poly(A)	7339–7608 (5'-UTR: 710–730 nt; ORF: 6543–6753; 3'-UTR: 87–111 nt); length of polyprotein: 2180–2250 aa.
Passerivirus	1	Passerivirus A	VPg + 5'UTRIRES[L1AB-1C-1D/2AH-box/NC-2B-2C/3A-3B-3C-3D]3'UTR-poly(A)	c. 6938 nt (5'-UTR: c. 420 nt; ORF: c. 6402 nt; 3' UTR: 136 nt); length of polyprotein: 2133 aa
Potamipivirus	1	Potamipivirus A	VPg + 5'UTRIRES[I 1 A B -1C-1D-2 A 1 n p g p/2A 2H-b ox/NC- 2B-2C/3A-3B-3C-3D]3'UTR-poly(A).	c. 8035 nt (partial) (5'-UTR: >415 nt; ORF: 7287 nt; 3' UTR: 334 nt); length of polyprotein: 2428 aa
Rabovirus	1	Rabovirus A	VPg + 5'UTRIRES-II[L1A-1B-1C-1D/2Apro-2B-2C/3A-3B-3C-3D]3'UTR-poly(A)	c. 7496 nt (partial) (5'-UTR: > 488 nt; ORF: 6777 nt; 3' UTR: 231 nt); length of polyprotein: 2259 aa
Rosavirus	1	Rosavirus A	VPg + 5'UTRIRES-II[L1AB-1C-1D-2Anpgp/2B-2C/3A-3B-3C-3D]3'UTR-poly(A).	7834 nt (5'-UTR: 751 nt; ORF: 7005 nt; 3'-UTR: 78 nt); length of polyprotein: 2335 aa
Sakobuvirus	1	Sakobuvirus A	VPg + 5'UTRIRES-IV[L1AB-1C-1D/2AHBox/NC-2B-2C/3A-3B-3C-3D]3'UTR-poly(A).	c. 8931 nt (5'-UTR: up to 828 nt; ORF: 7413 nt; 3' UTR: up to 795 nt); length of polyprotein: 2468 aa
Salivirus	1	Salivirus A	VPg + 5'UTRIRES-V[L1AB-1C-1D/2AHBox/NC-2B-2C/3A-3B-3C-3D]3'UTR-poly(A)	c. 7800 nt (5' UTR: 591 nt; ORF: 7059 nt; 3'-UTR: 157 nt); length of polyprotein: 2352 aa.

				c. 7032 nt (5'-UTR: 494 nt; ORF: 6405; 3'-UTR: 135 nt); length of polyprotein: 2134 aa

70%, respectively. It has been found through RNA hybridization studies that 5% genomic identity in all the human enterovirus (HEV) and 50% identity within groups (i.e., PV, coxsackieviruses A) (Young, 1973). Sequence studies have shown that 70% nucleotide similarity between the three types of PV (Stanway et al., 1983; Toyoda et al., 1984).

The similarity of an amino acid between coxsackieviruses B is found to be around 90% and with PV the similarity is around 60% (Iizuka et al., 1987; Jenkins et al., 1987; Lindberg et al., 1987). The coat of virion consists of four viral proteins (VP) according to the mobility in SDS polyacrylamide gels according to the decreasing molecular weight [i.e., VP1 (1D), VP2 (1B), VP3 (1C) and VP4 (1A)] (Liljas et al., 2002). The parenthesis in the VP position shows the standard nomenclature which is based on their position on the genome (Rueckert and Wimmer, 1984a, b). VP is referred to as structural capsid or coat proteins because of the composition of protein shell encapsulation with RNA genome. In PiVs the trace of fifth protein VPO (1AB) is present that undergoes breakage to yield VP2 (1B) and VP4 (1A) with the insertion of RNA into the capsid (Rueckert, 1976; Liljas et al., 2002). The major 4 virion proteins consist of 60 capsid subunits which termed protomers (Rueckert, 1976; Liljas et al., 2002) and each protomer has some portions of VP1-VP3 which is exposed on the surface whereas VP4 lies beneath the virion surface near RNA (Hogle et al., 1985; Rossmann et al., 1985; Rueckert, 1985). In the case of rhinovirus 14 human PiVs four neutralization antigenic sites have been found on the external surface of VPs. The identification of these sites has been carried out by sequencing viral escape mutants which neutralizes the monoclonal antibodies which lead to the identification of respective positions on the three-dimensional structure of the virus (Rossmann et al., 1985; Sherry et al., 1986; Liljas et al., 2002). It has been found that PVs shows just three neutralizing

epitopes (Hogle et al., 1985; Page et al., 1988; Liljas et al., 2002) and the viral receptor binding site was identified on the surface of virion and it seems to be like depression or canyon (Hogle et al., 1985; Rossmann et al., 1985). This canyon is found to be 25 Å which is, however, smaller than the diameter (35 Å) Fab fragment of the molecule of antibody. PiVs do not possess any envelope so, therefore, they are resistant to lipid solvents, whereas, human enterovirus (HEV) was found to be acid-stable ($\text{pH} \leq 3.0$). Due to this acid stability, they could easily pass through the stomach to cells lining in the small intestine where they replicate. Enteroviruses are easily inactivated when they are heated at 50 °C, desiccation and treatment with the disinfectants [i.e., formaldehyde (0.3%), HCl (0.1 N)] (Melnick, 1985). When HEV is centrifuged in sucrose gradients the sedimentation and buoyant density were found to be 156S and 1.34 g/mL in CsCl_2 (Rueckert, 1985; Liljas et al., 2002).

Receptors of PiVs

The entry of viruses is controlled by receptors and for PiVs they helped in cell attachment, signaling and endocytosis and the initiation of capsid alterations that are required for entry of infections (Racaniello, 1990; Evans and Almond, 1998; Rieder and Wimmer, 2002). The interaction between virus and receptor has been characterized for different viruses. In the case of the newly identified genera, the receptors have not been identified. Different receptors for PiVs include, i.e., immunoglobulin-like family, low density lipoprotein receptor (LDLR) family, integrin family of cell adhesion molecules, the complement control family and T cell immunoglobulin domain mucin like domain receptors (Rossmann et al., 2002; Tuthill et al., 2010a, b). These receptors and their nature of virus-receptor interactions, the plasticity of receptor usage, and role of receptors in the determination of host, tissue tropism and pathogenesis are described in the following sections.

Immunoglobulin superfamily receptors

Receptors of this group are well characterized for genus *Enterovirus* and adhesion molecule-1 (ICAM-1) is the major receptor for human Rhinoviruses (HRVs) (Greve et al., 1989; Staunton et al., 1989; Tomassini et al., 1989). The CD155 or nectin like molecule-5 (NECL-5) is the receptor of PV and plays an important role in cancer progression and embryonic development (Mendelsohn et al.,

1989; Gromeier et al., 2000; Takai et al., 2008). The receptor, coxsackie and Adenovirus (CAR) is the important part of the tight junction between cells in the epithelium (Coyne and Bergelson, 2005; Freimuth et al., 2008). It has been found that murine vascular cell adhesion molecule-1 (VCAM-1) is the receptor of the cardiovirus encephalomyocarditis virus (EMCV) (Huber, 1994). Type 1 membrane glycoproteins consist of 7 (VCAM-1), 5 (ICAM-1), 3 (PVR) or 2 (CAR) extracellular immunoglobulin like (Ig-like) domains, cytoplasmic and a transmembrane domain. Enterovirus receptors (ICAM-1, PVR, CAR) genetic alteration of molecules shows that the Ig-like domain is important for virus binding. Cryo-electron microscopy has been used to study the interaction of receptors with virus capsids and shows that receptors insert into the canyon (surface depression which encircles fivefold axes of enterovirus and rhinoviruses). This depression results in the greater surface area of interaction between receptor and canyon which increases the energy of the interaction in such a way that receptor binding could act as a trigger for the activation of capsid structural transitions that involved genome release and penetration of membrane. These Ig-like domain receptors help in the binding of the virus on the cell surface, which targets a specific endocytic pathway and activates the process of delivery of the genome to the cytoplasm. The interaction between EMCV and VCAM-1 and has been found that EMCV capsid does not possess a canyon which indicates that it is not necessary for the binding of Ig-like receptors.

Decay accelerating factor

Enteroviruses contain different receptors which are known as decay accelerating factors (DAF, CD55). These receptors are known as complement control family and are used as receptors for microbes and these receptors consist of four extracellular short consensus repeat modules that are attached to the membrane through glycosylphosphatidylinositol (GPI) anchor (Lea, 2002; Lindahl et al., 2000). As compared to the other virus-receptor interactions that are observed in the case of Ig-like receptors the mode of interaction of DAF is not well known. It has been found that different viruses have different binding sites on capsid and receptors (Lea, 2002; Powell et al., 1999). It is not necessary that the canyon is involved in the binding and also not initiate the changes in the capsid. The DAF function as the receptor is to recruit virus to the surface of the cell followed by interaction with co-receptor which is required for the initiation of entry of infectious agent.

Low density lipid receptor (LDLR) family

Low density lipid protein receptor (LDLR), LDLR-related protein (LRP) and very low density lipoprotein receptor (VLDLR) are known as receptors for HRVs (minor group) and possess the ability to hinder the binding of the virus to cultured cells (Hofer et al., 1994; Marlovits et al., 1998a, b, c). They consist of extracellular domains including 7LDLR, 8VLDLR or 31LRP ligand-binding repeats, cytoplasmic domain and transmembrane domain. There are multiple imperfect repeats that improve the capability of these molecules to bind effectively to various serotypes of the virus. The major group HRV/ICAM-1 interaction involves canyon for binding whereas LDLR binding does not involve canyon and also not induced any modifications in the capsid. Five copies of ligand-binding replicate and are thought to bound around the fivefold axis of symmetry to encapsulate the fivefold vertex so, therefore, the various less affinity circumstances merge to give greater affinity (Hewat et al., 2000; Konecsni et al., 2004; Querol-Audí et al., 2009; Rankl et al., 2008; Wruss et al., 2007). PiVs are capable to bind with various copies of a receptor to obtain a high affinity for binding. It has been found through phylogenetic analysis (PA) that 99 conventional HRV serotypes are grouped into two biological groups (HRV-A and HRV-B) (Vlasak et al., 2005; Palmenberg et al., 2009).

Integrins

Integrins are known as cell adhesion receptors that consist of a noncovalent heterodimeric complex in between subunits *a* and *b* (Akiyama, 1996). Subunit is made up of glycoprotein with a large globular extracellular domain, a small cytoplasmic domain and a transmembrane domain. Integrin receptor possesses a classical feature that is the identification of the Arg-Gly-Asp (RGD) tripeptide. Types of integrins i.e., $\alpha v\beta 1$, $\alpha v\beta 3$, $\alpha v\beta 6$, $\alpha v\beta 8$ could perform all the necessary functions as a receptor for the entry of the Aphthovirus FMDV (Jackson et al., 2000, 2004; Duque et al., 2004). Integrin $\alpha v\beta 6$ present on bovine epithelia and they are similar to the sites where lesions are developed during natural infection and it is the natural receptor for FMDV (Monaghan et al., 2005). The binding of integrin required an RGD triplet along with the near modification which is displayed by a flexible exposed loop (VP-1 G-H loop) on the surface of the capsid (DiCara et al., 2008; Logan et al., 1993). These receptor binding do not initiate the structural modification but helps in tethering the virus on the cell surface to facilitate its internalization by the process of endocytosis. Integrins as receptors were also helpful in the cell attachment of the Enteroviruses, Echovirus 1, Echovirus 9, CAV 9, Parechovirus and Human Parechovirus 1 (Bergelson et al., 1997; Triantafilou et al., 1999; Triantafilou and Triantafilou, 2001; Nelsen-Salz et al., 1999; Heikkilä et al., 2009; Roivainen et al., 1994; Williams et al., 2004; Joki-Korpela et al., 2001). These viruses bind integrins through RGD modification near the C-terminus of VP1 which is the exposed flexible site (Hendry et al., 1999). In the case of Echovirus 1 is an exception that binds with RGD independent integrin $\alpha_2\beta_1$ through interaction with canyon (Xing et al., 2004).

HAV cellular receptors

Cellular receptor for HAV (HAVcr-1) and human analog (huHAVcr-1) was found to be a novel class I integral membrane glycoproteins containing extracellular domain, N-terminal membrane distal Ig-like region and mucin like region (Kaplan et al., 1982; Feigelstock et al., 1998; Thompson et al., 1998). It has been found that HAVcr-1 is neutralized HAV and initiates HAV particle modifications (Silberstein et al., 2001, 2003). IgA is a natural ligand of HAVcr-1 and it increases the HAV receptor interactions (Tami et al., 2007). The huHAVcr-1 is classified into prototype members of the T cell immunoglobulin domain, mucin like domain (TIM)

gene family or TIM-1. The study has shown that childhood infection with HAV initiates TIM-1 and protects against allergy in later life that leads to the decreased incidence of HAV in western countries which is responsible for allergy and asthma (McIntire et al., 2004).

EV 71 receptors

EV71 is a type of Enterovirus that causes hand, foot and mouth diseases with normal with relatively mild and self-limiting symptoms. In some cases, the EV71 infection is linked with severe and fatal neurological diseases. There are two receptors reported for EV71 which are human P-selectin glycoprotein ligand-1 (mucin like protein) and serve as EV71 infection of leukocytes and scavenger receptor (class B member 2) which are used for endocytosis of high density lipoprotein (Nishimura et al., 2009; Patel and Bergelson, 2009; Yamayoshi et al., 2009).

Sialic acid

Salic acid (SA) is present on the oligosaccharide chains that trim a variety of glycoproteins of the cell surface. The Cardiovirus Theiler's murine encephalomyelitis virus (TMEV) accepts SA as a receptor and the complex formed between SA and virus has been characterized by crystallography (Zhou et al., 2000; Lipton et al., 2006). EMCV (Cardiovirus) binds through SA with glycoprotein A that is a receptor molecule on virus nonpermissive mammalian erythrocytes (Tavakkol and Burness, 1990). It has been found that EMCV could use the SA mediated entry after cell culture adaptation (Guy et al., 2009). *Aphthovirus* equine rhinitis A virus (ERAV) attach to cells through an interaction with SA and the complex formed between virus and SA is characterized by X-ray crystallography (Warner et al., 2001; Stevenson et al., 2004).

Co-receptors

It is necessary for the productive infection that some DAF binding *Enteroviruses* required co-receptors to affect the modification of capsid structure. It has been found that *Coxsackieviruses*, CAV21 and CBV3 use Ig-like molecules such as ICAM-1 and CAR, respectively, as co-receptors (Shafren et al., 1997a, b, c). DAF (primary receptor) along with co-receptors also bind with the canyon and initiates the capsid modifications. Cultures cell studies have shown that viruses could infect through co-receptors in DAF absence (Shafren et al., 1997a). A study on CBV3 infection of polarized epithelial cells has been carried out and it has been found that CAR is found in its natural location in the tight junctions between cells and not accessible to the virus. The binding of DAF initiates signaling dependent transport of the receptor-virus complex to the tight junctions for the interaction between CAR and cell entry could happen (Powell et al., 1998; Ward et al., 1998; Goodfellow et al., 2000; Coyne and Bergelson, 2006). Integrin-binding enteroviruses also required co-receptors for their entry and studies have been shown that CAV9 required β_2 microglobulin, MHC-I-associated protein GRP78 and MHC-I (Hughes et al., 1995; Triantafyllou et al., 1999, 2002).

Diseases caused by PiVs

PiV family consists of Enteroviruses, Hepatoviruses, Parechoviruses and Rhinoviruses (human pathogens) while Aphthoviruses and Cardioviruses (animal pathogens). On the basis of their pathogenicity these human Enteroviruses are subgrouped into polioviruses (PV, 3 serotypes), Coxsackie A viruses (CAV, 23 serotypes), Coxsackie B viruses (CBV, 6 serotypes), Echoviruses (EV, 28 serotypes) and Enteroviruses 68–71. *Enteroviruses* caused infections in man that varies from minor respiratory illnesses to paralysis, myocarditis, meningoencephalitis, other infections that lead to multiple organ failure in newborns, poliomyelitis, hand foot and mouth diseases (caused by CAV16), acute hemorrhagic conjunctivitis (caused by CAV24, Enterovirus 70), herpangina (caused by CAVs) and pleurodynia (caused by CBVs) (Grist et al., 1978). More than 100 human *Rhinovirus* (HRV) serotypes are known and considered to cause the common cold. HRV mainly caused sinusitis, otitis media and exacerbation of asthma (Minor, 1991; Hyypää et al., 1992; Stanway et al., 1994; Mayo and Pringle, 1998; Pitkäranta and Hayden, 1998). Different disease infections caused by PiVs are given in Table 8.

Detection of PiVs

The standard methods of diagnosis for human PiVs infections are culturing of the virus in infected cell lines which are followed by neutralization typing (Enteroviruses, Parechoviruses) or acid lability testing (HRVs). The indirect evidence of the etiology of the diseases is shown by the serological detection of Enteroviruses specific antibodies. Specific IgM class antibodies are used for the diagnosis of HAV infections. Current methods which are used for the PiVs infections are laborious, insensitive, time consuming and inconvenient. So, therefore, newly developed molecular techniques for PiVs diagnosis were found to be faster, specific and sensitive.

Reverse transcriptase polymerase chain reaction (RT-PCR)

It has been found that sequence analysis and the cDNA clones for the diagnosis of the various Enterovirus serotypes through one single probe had proposed that a few regions of the genome are very similar to the other members of the genus. However, it has also been found that HRVs were found to be similar to the HEVs and based on these examinations the efforts were carried out for the selection of primers and probes that are used to develop the RT-PCR as a diagnosis test.

The genome of PiVs consists of 7000–9000 nucleotides (nt) and single stranded RNA molecules. The PiVs long reading frame coding for the capsid and nonstructural proteins is followed by the NCR. This region also contains several modifications that

Table 8 Diseases caused by PiVs (Santti et al., 1999).

<i>Virus</i>	<i>Diseases</i>
Polioviruses 1, 2, 3	Poliomyelitis
Coxsackievirus A7, Enterovirus 70, 71	Paralytic diseases
Enterovirus serotypes	Meningitis/encephalitis
Coxsackie B viruses	Myocarditis
Coxsackie B viruses, echoviruses	Neonatal infection
Coxsackie B viruses	Pleurodynia
Coxsackie A viruses	Herpangina
Coxsackievirus A16, Enterovirus 70	Hand foot and mouth disease
Coxsackievirus A24, Enterovirus 70	Acute hemorrhagic conjunctivitis
Many enteroviruses, parechoviruses	Respiratory infections
Rhinoviruses	Common cold
Parechovirus 1	Gastroenteritis
Hepatitis A virus	Acute hepatitis

formed the secondary structures that are required for translation and replication of the virus. The RT-PCR test used these homologous regions that are similar in *Enteroviruses* and *Rhinoviruses*. The modification of the products has been found to form a similar length form for which an oligonucleotide probe is required that discriminate between two PiVs groups (Hyypia et al., 1989; Santti et al., 1997). However, a primer is targeted to save the VP2 capsid protein gene that is used along with another primer from NCR (Olive et al., 1990). There is an advantage in the pairing up of these primers because in Enteroviruses and Rhinoviruses amplicons are different in the length. Therefore, it has been found in different studies that all Enterovirus serotypes and HRV isolates could be detected using these formed primers sequences (Fig. 4) (Hyypia et al., 1989, 1998; Horsnell et al., 1995; Pulli et al., 1995; Arola et al., 1996; Huttunen et al., 1996; Pitkäranta et al., 1997; Oberste et al., 1998).

In 1996, with the outbreak of aseptic meningitis (AM) in Finland the effectiveness of this technique has been proven. The specimen collected from the patients include cerebral spinal fluid (CSF), throat swabs, stool samples and sera and it has been found that the *Enterovirus* is the causative agent in CSF by RT-PCR (Arola et al., 1996).

Sequence analysis

It has been found through the analysis of the Enterovirus genome that the members of this genus formed four genetic clusters in the coding region when used for comparison. These genetic clusters are subdivided into four subgroups (A, B, C1, C2 and D). Cluster A includes CAV serotypes and Enterovirus 71 and cluster B contains CAV9, CBVs and EVs. However, cluster C1 and C2 are related to each other containing Polioviruses and CAVs and cluster D consists of Enterovirus 70 (Hyypä et al., 1997). It has been found through partial sequence analysis that all Enterovirus belongs to these four clusters (Pulli et al., 1995; Huttunen et al., 1996) and VP4:VP2 region sequence has been used for the molecular typing of the clinical isolates (Arola et al., 1996). However, Polioviruses could not be differentiated from CAVs in cluster C by this analysis and so, therefore, other genomic regions are required. In NCR (5%) the *Enterovirus* serotypes clustering are not a useful tool for typing but could be used in epidemiological studies. Genetic clustering could also be used in the detection of HRVs and the relation of this group with pathogenicity of the infection is not clear (Horsnell et al., 1995). Partial sequence analysis (PSA) is widely used in the epidemiological studies for PV and helps in the building up of the large sequence database (Rico-Hesse et al., 1987; Zheng et al., 1993; Huovilainen et al., 1995; Kew et al., 1995; Mulders et al., 1995; Chezzi et al., 1997; Morvan et al., 1997; Fiore et al., 1998). 150 nt region in the junction of the structural gene VP1 and the 2A viral protease gene has been used universally for these studies (Rico-Hesse et al., 1987).

Enterovirus

A febrile illness has been developed by Franklin Delano Roosevelt during his summer vacations and this illness then leads to paralysis. This is one of the most commonly recognized cases of paralytic poliomyelitis and polio was discussed in 1580 BCE.

Fig. 4 Representation of PiVs genome and the location of the RT-PCR used for the detection of human enteroviruses (HEVs) and rhinoviruses (HRVs).

In 1949 for the first time, this virus has been grown in tissue culture by John Enders. This isolation is then followed by identification of the prototypic Enterovirus (EV) and then other members of this family have been studied and their properties are characterized. It has been more than 70 years that animal Enteroviruses (EVs) and EV like agents are known for causing diseases. Virulent pig polioencephalomyelitis for the first time was reported in Czechoslovakia in 1929 and in 1932 avian encephalomyelitis was reported in the USA. Tissue and egg culture techniques discovery help in the isolation and biological characterization of these viruses.

EVs are nonenveloped, single-stranded RNA, icosahedral shape and small (30 nm) in size viruses that belong to the family of *Picornaviridae*. It causes a variety of diseases and consists of more than 70 serotypes (Wilfert et al., 1983; Palacios and Oberste, 2005). They are widely distributed around the globe (Rotbart and Hayden, 2000). The infections caused by EVs are mostly mild (i.e., febrile illness, respiratory infections, hand foot mouth diseases, herpangina, etc.) with complete recovery but they can also cause severe and life threatening diseases including encephalitis, myocarditis, neonatal sepsis, polio and meningitis (Table 9) (Lake et al., 1976; Melnick, 1996a, b; Rotbart, 1995a, b; Why, 1995; Sawyer, 1999). EVs include *Polioviruses*, *Coxsackie A* and *B*, *ECHO* viruses and numbered EVs. They are also linked with various other conditions which include chronic autoimmune diseases (i.e., diabetes mellitus I, polymyositis, dermatomyositis, Sjogren's syndrome), cardiovascular diseases (i.e., chronic dilated cardiomyopathy, atherosclerosis, ventricular arrhythmias, transplant rejection) and neurological diseases (i.e., amyotrophic lateral sclerosis) (Palacios and Oberste, 2005). EVs are transmitted from one to another person via air or oral fecal route and the infections caused by them are also possible through contaminated objects.

Classification of EVs

In 2012, the classification of EVs taxonomy was reported by the International Committee on Taxonomy of Viruses (King et al., 2012; Adams et al., 2013, 2014, 2015, 2016). EV belongs to the family of *Picornaviridae* which includes 10 enterovirus species (i.e., Enterovirus A, B, C, D, E, F, G, H, I, J) and 3 rhinovirus species (i.e., Rhinovirus A, B, C). The various serotypes of different EVs are reported in Table 10. There are certain unclassified species of EVs which include monkey EV (SV-47), EV-122 and EV-123 because their genome sequence is not clear and is not matched with existing species (Nikonov et al., 2017).

Serotypes of EVs

Human EVs are subdivided into polioviruses, coxsackieviruses group A, B and echoviruses. However, in 1969 the serotypes of EVs did not previously allocate to the above mentioned groups so, therefore, these serotypes are designated as EV followed by number 68 (Almond and Yin-Murphy, 1999; Sun et al., 2019). There are four serotypes of EVs (EV68–71) which are in the genus EV of the family *Picornaviridae*. These serotypes are described in the following sections.

EV 68 (EV-D68)

Initially, the first isolated prototype of EV68 is called as Fermon virus and in 1962 it was isolated in California from the four children suffering from pneumonia and bronchiolitis (Schieble et al., 1967). This virus was isolated and characterized by the throat swab samples of the children and this result in the detection of four new distinct virus strains i.e., Fermon, Franklin, Robison and Rhyne. The statistics reported by the US National Enterovirus Surveillance System (NESS) 26 cases of EV 68 have been reported from 1970 to 2005 (Midgley et al., 2015). In 2014 the highest number (~1153) of EV-D68 infections has been reported with severe respiratory

Table 10 List of EVs species and there serotypes (Nikonov et al., 2017).

Species	Number of species	Serotypes
Enterovirus		
A	25	A2 (CV-A2), CV-A3, CV-A4, CV-A5, CV-A6, CV-A7, CV-A8, CV-A10, CV-A12, CV-A14, CV-A16, enterovirus A71 (EV-A71), EV-A76, EV-A89, EV-A90, EV-A91, EV-A92, EV-A114, EV-A119, EV-A120, EV-A121, simian enteroviruses SV19, SV43, SV46, baboon enterovirus A13 (BA13)
B	63	Coxsackievirus B1, CV-B2-B6, CV-A9, echovirus 1 (E-1), E-2-E-7, E-9, E-11-E-21, E-24-E-27, E-29-E-33, enterovirus B69 (EV-B69), EV-B73-EV-B75, EV-B77-EV-B88, EV-B93, EV-B97, EV-B98, EV-B100, EV-B101, EV-B106, EV-B107, EV-B110 (from chimpanzee), EV-B111, EV-B112 (from chimpanzee), EV-B113 (from mandrill), simian enterovirus SA5
C	23	Poliovirus (PV) 1, PV-2, PV-3, coxsackievirus A1 (CV-A1), CV-A11, CV-A13, CV-A17, CV-A19, CV-A20, CV-A21, CV-A22, CV-A24, EV-C95, EV-C96, EV-C99, EV-C102, EV-C104, EV-C105, EV-C109, EV-C113, EV-C116, EV-C117, EV-C118
D	05	EV-D68, EV-D70, EV-D94, EV-D111 (from human and chimpanzee), EV-D120 (from gorilla)
E	05	EV-E1, EV-E2, EV-E3, EV-E4.
F	07	EV-F1, EV-F2, EV-F3, EV-F4, EV-F5, EV-F6, EV-F7
G	16	EV-G1, EV-G2, EV-G3, EV-G4, EV-G5, EV-G6, EV-G7, EV-G8, EV-G9, EV-G10, EV-G11, EV-G12, EV-G13, EV-G14, EV-G15, EV-G16
H	04	SV4, SV28, SA4, A-2 plaque virus
I	01	<i>Camelus dromedarius enterovirus</i> (camel enterovirus)
J	06	SV6, EV-J103, EV-J108, EV-J112, EV-J115, EV-J121
Rhinovirus		
A	80	A1, A2, A7-A13, A15, A16, A18, A19-A25, A28-A36, A38-A41, A43, A45-A47, A49-A51, A53-A68, A71, A73-A78, A80-A82, A85, A88-A90, A94, A96, A100-A109
B	32	B3-B6, B14, B17, B26, B27, B35, B37, B42, B48, B52, B69, B70, B72, B79, B83, B84, B86, B91-B93, B97, B99-B106
C ^a	01	HRV-A2, HRV-C or HRV-X

^aOn the bases of certain test the authors considered it same like *Rhinovirus A* (Arden et al., 2006; McErlean et al., 2007) and others preferred to mention it as HRV-C (Lamson et al., 2006; Lau et al., 2007; Lee et al., 2007; McErlean et al., 2008) or HRV-X (Kistler et al., 2007).

symptoms (Midgley et al., 2015). Various retrospective studies have been carried out which shows the greater prevalence of EV-D68 infection in Europe in the same period (Poelman et al., 2015). The most common clinical infection caused by EV-D68 is respiratory illness (Oberste et al., 2004).

EV-D68 consists of a positive single stranded RNA which is about 7.6 kb and it contains a single ORF like other picornaviruses. This ORF is associated with untranslated regions (UTR) on each end (Opanda et al., 2014). This association results in the encoding a precursor polypeptide which further autoanalytically breakdown to form structural proteins (VP1 to VP4) and seven other nonstructural proteins (2A, 2B, 2C, 3A, 3B, 3C, 3D) (Fig. 5). VP1 consists of serotype specific neutralization BC loop site which is used to differentiate between virus serotypes and to identify the new strains (Tokarz et al., 2012). 2C viral protein has been found to play an important role in the infection process and host-viral interaction and this helps in the targeting of anti EV-D68 drugs (Sun et al., 2019). EV-D68 is subdivided into four subtypes and many branches such as original classical subtypes and epidemic related branches (Clade A, B, C, D). These subtypes are widespread in American, Europe and Asia. It is acid labile, favors lower growth temperature and it multiplies in the respiratory tract which is also a typical attribute of human rhinoviruses. Therefore, EV-D68 shows the same important biological and molecular properties as other enteroviruses and rhinoviruses (Oberste et al., 2004).

EV 69

First time in 1969 the EV 69 prototype (Toluca-1 virus) and two other isolates have been found in the rectal swab of healthy 4 year old children in Toluca, Mexico (Rosen et al., 1973; Melnick et al., 1974; Yin-Murphy and Almond, 1996). It is an uncommon virus and seven isolations have been carried out in the countries during the period of 1975–1983. In Australia (Fairfield Hospital, Victoria) one isolation (1979) and WHO collaborating center for Virus Reference and Research, Singapore has identified two strains in 1984 (Almond and Yin-Murphy, 1999; Yin-Murphy and Almond, 1996). EV 69 could be isolated from feces and nasopharyngeal aspirates and produces the EV cytopathic effects (CPEs) in rhesus kidney, Hep-2 and Hela cell cultures. The cross section antigenically with one of these groups (i.e., coxsackie B, coxsackie A9 viruses) has been previously reported. In the case of

Fig. 5 Representation of the enterovirus 68 (EV D68) genome (Sun et al., 2019).

Toluca-1 antiserum with homologous hemagglutination inhibition (HI) and neutralization (N) shows the titers of 1.320 and 1.500, respectively, whereas in the case of echo 6 D1 the titer was found to be 1.400 and 1.500 for HI and N, respectively (Almond and Yin-Murphy, 1999; Yin-Murphy and Almond, 1996). However, in the case of D1 (cox) antiserum has been found to show the titer of 1.50 for homologous HI and N. The Toluca-1 has been found to show the titer of <1.100 and <1.500 for HI and N, respectively, whereas E6 agglutinates human erythrocytes shows high titers at 37 °C than at lower temperature (4 °C) (Almond and Yin-Murphy, 1999; Yin-Murphy and Almond, 1996). However, Toluca-1 shows the highest titer at a lower temperature than at a higher temperature. The Toluca EV 69 strains have been found in the feces of healthy children and the Australian (1979) and Singapore (1984) strains have been isolated from nasopharyngeal aspirates of infants with respiratory illness. The transmission of this virus is through oral-fecal and respiratory routes (Almond and Yin-Murphy, 1999; Yin-Murphy and Almond, 1996).

EV 70

EV 70 is the causative agent of acute hemorrhagic conjunctivitis (AHC) and was first isolated in 1971 during the wave of AHC in Morocco, Singapore, Hong Kong and Japan. It has been found that EV 70 played an important role in the 1980–1982 AHC pandemic in Africa, Southeast Asian countries, India and the Middle East (Almond and Yin-Murphy, 1999). The outbreak of AHC caused by EV 70 has not been reported in Australia and mostly AHC epidemic occurs in hot and humid areas. The spread of conjunctivitis is mostly occurring due to unhygienic conditions, poor personal hygiene and overcrowding. It possesses similar physicochemical properties to enteroviruses and electron micrographic studies revealed that it is a nonenveloped virion having 22–27 nm diameter with icosahedra symmetry. The buoyant density in cesium chloride and sedimentation coefficient in sucrose was found to be 1.34 g/mL and 160 S, respectively (Almond and Yin-Murphy, 1999). EV 70 has been found to be inactivated through phenol, cresol, formaldehyde, chlorine at the concentration of 1 ppm in distilled water, methanol (50%), phenol (70%), iodine (0.004%) in DIASAN (Almond and Yin-Murphy, 1999). The replication of EV 70 has been found to be inhibited by interferon β , arildone {4-[6–2-chloro-4-methoxyphenoxy]hexyl}-3,5-heptanedione}, RO 09-0179 (4',5-dihydroxy-3,3',7-trimethoxyflavone), benzimidazoles-enviroxime, envirodone and guanidine hydrochloride. However, actinomycin D, benzalkonium chloride, benzethonium chloride, chlorhexidine gluconate and hexachlorophene do not show any inhibitory effect on the replication of EV 70 (Almond and Yin-Murphy, 1999).

EV 70 contains positive sense single stranded RNA having typical EV organization. It possesses 5'-NCR of 726 nucleotides, a long open frame of 6582 nucleotides and 3' NCR of 82 nucleotides earlier to the poly (A) tract. VPg protein is covalently attached to the virion RNA. EV 70 icosahedral virion is formed by the 60 copies of four viruses encoded proteins 1A (Vp4, 9kD), 1B (Vp2, 28kD), 1C (Vp3, 27kD) and 1D (Vp1) (Almond and Yin-Murphy, 1999). The formation and breakdown pathway of virus encoded proteins was found to be following the L434 system with glutamine glycine as the breakdown site. CD55 has been identified as a receptor on Hela cells for EV 70 and GPI-anchored cells surface protein is found to be a natural regulator of complement action. The functions of these GPI-anchored cell is via decay of C3 and C5 convertases in classical and alternative pathways of complement fixation. EV 70 virus has been found to be similar to echoviruses (i.e., E6, E7, E13, E21, E29, E33) (Almond and Yin-Murphy, 1999). The optimal temperature for the growth of EV 70 has been found to be 33 °C whereas at higher temperature (>39 °C) the viral synthesis is hinder and stops the replication (Almond and Yin-Murphy, 1999). The in vitro experiments show that the temperature dependent step is the uridylation of VPg. It has been found that EV 70 from conjunctival swabs and scrapings, throat swabs and feces made cytopathic effects (CPEs) in the tissue cell culture of human and simian origin and Hela cells are in this case are preferred cell lines (Almond and Yin-Murphy, 1999).

EV 71

From 1969 to 1972 in California EV 71 has been found as a causative agent for CNS disease [i.e., aseptic meningitis (AM), encephalitis] (CDC, 1985). The prototype EV 71 strain (BrCr/1970) was isolated from the culture taken from the brain in severe cases of encephalitis. EV 71 is widely spread in the world and has been found to the causative agent of AM, hand foot mouth disease (HFMD), respiratory illness, polyneuritis and encephalitis in New York (1972) and Australia (1972–1973, 1978, 1979, 1982–1983, 1986) (CDC, 1986a, b). In Sweden (1972), Japan (1973, 1978) and Bulgaria (1975) poliomyelitis like paralysis has been caused by EV 71 which results in a high fatality rate in the children (Almond and Yin-Murphy, 1999). EV 71 has been found to be linked with the epidemic of tick borne encephalitis in Hungary (1978), respiratory infections associated with CNS diseases in France (1989), HFMD in China (1989) and Singapore (1984), monoplegia in Hong Kong (1987) and viral encephalitis (1996) (Almond and Yin-Murphy, 1999). The physicochemical properties of the EV 71 viruses are similar to the EV group. The nucleotide sequence of the EV 71 has been determined and found that it is similar to coxsackieviruses A16 and A2. The replication, receptor recognition and 3D structure of the EV 71 are not different than other EVs (Almond and Yin-Murphy, 1999). The presence of EV 71 in throat swabs, spinal cord, tissue from brain, mesenteric lymph nodes, skin vesicles and CSF has been found to produce CPEs in kidney cell cultures of monkey, Hela and HEL cell lines and human fetal kidney. It has been found that an incubation temperature of 35 and 39 °C in patients with encephalitis leads to CPEs production (Chumakov et al., 1979a, b). However, the strains of HFMD grow at 35 °C but not at 39 °C. The strains of EV 71 related to BrCr/71 are different antigenically from other classification of EVs and are evaluated with neutralization and immunodiffusion assays (Almond and Yin-Murphy, 1999).

EV 71 viruses are the type of EVs that are capable of causing various ailments in a pandemic or occasional portion. It majorly causes AM along with bulbar spinal dysfunction and polyneuritis. EV 71 also causes the outbreak of HFMD with or without has been found to be linked with encephalomyocarditis and respiratory illness (Almond and Yin-Murphy, 1999). It has been found that the transmission of EV 71 is mostly through oral fecal, respiratory routes and from lesions on the skin. In response to EV

71 infections, the neutralizing antibodies are produced and due to high incubation time in CNS disease, the high antibody titers have been observed in neurological disease (Almond and Yin-Murphy, 1999). The clinical manifestations linked with EV 71 are listed Table 11.

Physical, biochemical and biological characteristics of EVs

EVs possess similar properties like *Picornaviridae* such as small in size (22–30 nm), single stranded RNA, naked nucleocapsid (lack of envelope) and intolerance to ether and lipid solvents. Therefore, it indicates that the EVs do not possess essential lipids. Nondestructive methods have been used to evaluate the diameter of hydrated and wet virus particles (Rueckert, 1985; Jubelt and Lipton, 2014). The nucleic acid present in the EVs constituting around 30% of the particle mass with a molecular weight of 2.3–2.8 million. PVs contain 12 genes whereas poxviruses possess 400 genes. This virus mature in the cytoplasm and an ineffective nucleic acid present in EVs and Rhinoviruses is isolated. This isolated nucleic acid is liberated on the surface protein antigen and such RNA could not be neutralized via antiserum with the intact virus. Humans are mostly infected by EVs and *Rhinoviruses* and these genera are found to be different in various properties. However, it has been found that EVs are stable at pH 3–5 (for 1–3 h) but *Rhinoviruses* are found to be acid labile. In infected humans, EVs are found in the alimentary tract (i.e., lower intestine and throat) whereas Rhinoviruses are majorly found in the nose and throat but rarely present in fecal specimens. EVs grew at 36–37 °C in stationary cultures but Rhinoviruses are incubated on roller drums at 33 °C in fetal cell cultures (Hamre and Procknow, 1963; Hamre et al., 1966; Hamre, 1968). It has been found that EVs and *Rhinoviruses* are stabilized by magnesium chloride against thermal inactivation whereas in cesium chloride EVs and *Rhinoviruses* possess the density of 1.34 and 1.40 g/mL, respectively. The physical and biochemical properties of human *Enteroviruses* (HEV) are reported in Table 12.

Replication cycle of EVs

Virions and viral genome organization

The viral genome of EVs possessess a single ORF along with highly structured untranslated regions (UTR) on the position of 5'- and 3'-poly (A) tail. This viral genome is uncapped and 5'- end is covalently bound with 3B viral protein which is called as VPg (viral protein genome linked). Internal ribosomal entry site (IRES) is present in 5'-UTR which helps in the cap independent translation. The ORF is the same in all PiVs, however, there are some differences in each genus. EVs ORF contains polypotein with structural proteins VP1–4 at P1 region. The nonstructural proteins 2A–2C and 3A–3D are present at P2 and P3 regions, respectively (van der Linden et al., 2015).

Table 12 Physical and biochemical properties of HEVs (Jubelt and Lipton, 2014).

Diameter	30 nm
Shape	Spheroidal
Symmetry	Icosahedral
Envelope	None
Virion proteins	VP1, VP2, VP3, VP4
Protein subunits	60
Protomer compositions	One copy of the four virion proteins
Nucleic acid	Single stranded linear RNA
Percent RNA per virion (%)	30
Percent protein per virion (%)	70
Reaction of ether and lipid solvents	Resistant
pH stability	3–9
Buoyant density (g/mL)	1.34 in cesium chloride
Sedimentation coefficient	156S

Translation and processing of protein

The replication cycle of EV is propagated via linkage to a receptor (Tuthill et al., 2010a, b). The receptors bound at depression in the capsid which is known as a canyon and it is surrounded by fivefold axis of symmetry. After this, the virus is then internalized and the viral RNA is released into the cytoplasm. The produced single polypeptide is processed through a proteolytic mechanism by the proteases 2A^{Pro} and 3C^{Pro} which results in the release of structural and nonstructural viral proteins and stable precursors. The viral proteases also help in the cleavage of cellular targets which improve the environment for viral proliferation. Blockage of translation of cellular proteins (host shut off) occurs with the cleavage of eIF4E and poly (A)-binding proteins (PABP) by 2A^{Pro} and 3C^{Pro} (Kräusslich et al., 1987; Lloyd et al., 1988; Joachims et al., 1999; van der Linden et al., 2015). Viral proteases also breakdown various cellular factors that help in the virus reproduction and hinder antiviral responses (Badorff et al., 1999; Barral et al., 2007; Castelló et al., 2011; Mukherjee et al., 2011; Lei et al., 2013; Wang et al., 2013; van der Linden et al., 2015).

EV RNA replication

The nonstructural proteins initiate the replication of the viral genome and uridylation of protein primer VPg begins the RNA genome replication through the viral RNA dependent RNA polymerase 3D^{Pol} with secondary RNA structure in the genome which is called as cis-acting replication element (cre) as a template (Gerber et al., 2001; Paul et al., 2000; Rieder et al., 2000; Yang et al., 2002; van der Linden et al., 2015). 3D^{Pol} helps in the elongation of VPgUpU which produces the negative stranded intermediates that are used as a template for the formation of positive stranded RNA molecules. These positive stranded RNA molecules entered in another process of translation and replication could be wrapped up in the capsids which results in the production of infectious virus particles (van der Linden et al., 2015).

Role of viral proteins and host factors in membrane rearrangements

In the case of positive stranded RNA viruses, the replication of viral RNA occurs at cellular membranes that are recognized in virus infection (Belov and van Kuppeveld, 2012; Paul and Bartenschlager, 2013; van der Linden et al., 2015). It has been found that in infected cells the single and double membranous structures are present (Belov and van Kuppeveld, 2012; Paul and Bartenschlager, 2013; van der Linden et al., 2015). The studies of electron tomography with PV and CB3 shows that in early infection the single membranous tubular structures are present, however, in later stages these structures flatten, curve and fuse to form double membrane vesicles (DMV) (Belov and van Kuppeveld, 2012; Paul and Bartenschlager, 2013; van der Linden et al., 2015). These DMV further wrapped into multilamellar structures by multiple additional cisternae. The formation of these structures has not been clear yet but evidence has been presented that they are either formed in the early secretory pathway or by the autophagy pathway. The electron tomography studies indicate that somehow these theories are correct that early secretory pathway the role of Brefeldin A (BFA) which is an inhibitor of endoplasmic reticulum (ER) to Golgi transport which stop the EV replication (Irrazun et al., 1992; Gazina et al., 2002; Belov et al., 2008; Lanke et al., 2009; van der Linden et al., 2015). Various proteins from the pathway are necessary for the virus replication and could be found on replication organelles. Golgi specific BFA resistance factor 1 (GBF1) stimulated the GTP exchange of the GTPase ADP ribosylation factor 1 (Arf 1). The activation of Arf 1-GTP results in the membrane bound that mediates the effector proteins (i.e., COP-1 coat complex) to initiate the production of the secretory pathway. Thus Arf 1 is the key regulator of protein and lipid transport in the early secretory pathway. During infection viral protein 3A select GBF-1 and indirectly Arf 1 for replication organelles via direct interaction with GBF1 (Belov et al., 2008; Wessels et al., 2006a, b). This leads to the loss of COP-1 from membranes which results in the interference of secretory pathways and hindrance of the secretion of protein (Wessels et al., 2005, a; Doedens and Kirkegaard, 1995; Hsu et al., 2010; van der Linden et al., 2015).

Another Golgi localized protein, phosphatidylinositol-4-kinase III beta (PI4KIII β) is found to be an important host factor for the replication of EV (Hsu et al., 2010). This protein is a kinase that helps in the synthesis of phosphatidylinositol-4-phosphates (PI4P). PI4P lipids as a precursor of PI(4,5)P₂ are part of PI3K and phospholipase C signaling pathways and also select the proteins with PI4P binding pleckstrin homology (pH) domain to membranes. This selection is for the membrane biogenesis, lipid homeostasis and vesicle mediated trafficking on the Golgi complex (D'Angelo et al., 2008; Graham and Burd, 2011; Santiago-Tirado and Bretscher, 2011; Dorobantu et al., 2014). PI4KIII β in infection selected for the replication sites by 3A and which increase in the level of PI4P lipids (Hsu et al., 2010). This selection of PI4KIII β is not dependent on the GBF1, Arf1, and ACBD3 factors (Téoulé et al., 2013; Dorobantu et al., 2014; van der Linden et al., 2015).

Oxysterol-binding protein (OSBP) is PI4P binding protein that transfers PI4P lipids formed by PI4KIII β through Gogi complex in the ER in return of cholesterol which is transported to the other direction (Mesmin et al., 2013). Some other studies carried out show that OSBP bounds to PI4P enriched replication organelles to initiate PI4P/cholesterol exchange between ER and membranes (Arita, 2014; Roulin et al., 2014; Strating et al., 2015; van der Linden et al., 2015). Therefore, this exchange in cholesterol increasing its concentration and endosomal cholesterol accumulate the cholesterol in the membranes of the replication (Illytska et al., 2013; Roulin et al., 2014; Albulescu et al., 2015). The concentration of cholesterol in membranes regulates the fluidity of membranes and leads to the formation of lipid microdomains. The virus initiates the deposition of cholesterol which induces the deformation of membranes which helps in the generation of replication organelles (van der Linden et al., 2015).

Ontogenesis and virus liberation

The synthesized viral RNA with positive polarity encapsulated via capsid proteins leads to the formation of virions. This process combines with active replication to encapsulate the newly synthesized genomes (Molla et al., 1991; Nugent et al., 1999; van der Linden et al., 2015). This process is not controlled by RNA encapsidation signal or RNA protein interaction but through an interlinking between 2C which is located in the replication complex and the capsid VP3 protein (Liu et al., 2010). The new virions assemble with the release of P1 capsid precursor through the polyprotein. These assemble virions are then folded using chaperone protein HSP 90 and refined by 3C^{Pro} which results in the production of VP0, VP1 and VP3 (Ypma-Wong et al., 1988; Geller et al., 2007a, b; van der Linden et al., 2015). This voluntary process results in the formation of protomers by the assembling of the capsid proteins and 5 protomers combine to form pentamer which leads to the formation of provirion. All EVs required glutathione for the production and stability of the pentamers (Mikami et al., 2004; Smith and Dawson, 2006; Thibaut et al., 2014; Ma et al., 2014) and the last step is the virion maturation via RNA induced cleavage of VP0 into VP2 and VP4 which yields infectious viruses. This last step is boosting up by the acidic environment in autophagosome DMVs (Richards and Jackson, 2012; van der Linden et al., 2015). These infectious viruses are then released in the environment through the process of host cell lysis and nonlytic release via DMVs and the release of phosphatidylserine lipid containing vesicles encapsulated with virions (Feng et al., 2013; Robinson et al., 2014; Chen et al., 2015; van der Linden et al., 2015).

Diagnosis of EVs

There are number of laboratories around the globe working to perform the diagnostic test for EVs so, therefore, these tests should be standardized (Harvala et al., 2017). The recommended sample types used for the diagnosis of EVs infections are reported in Table 13 and the details of the molecular assay diagnostic methods are discussed below.

RT-PCR

RT-PCR is a sensitive method used for the detection of EVs in clinical samples and is more sensitive than cell culture (Chonmaitree et al., 1988; Beld et al., 2004; Iturriza-Gómara et al., 2006). The detection of EVs RNA via RT-PCR is based on the targeting of 5' NCR and, therefore, helpful in the detection of all types of EVs (Iturriza-Gómara et al., 2006; Van Doornum et al., 2007; Nijhuis et al., 2002; Janes et al., 2014; Jaramillo-Gutierrez et al., 2013). It is important to prepare the correct sample before the extraction of nucleic acid and the detection of EVs specifically for stool samples that should be disaggregated in buffer and filtered via centrifugation to hinder PCR inhibition. Internal control (IC) is added for the identification of inhibitory compounds in the

Table 13 Clinical samples used for the detection of EVs in different ailments (Harvala et al., 2018).

<i>Clinical samples</i>	<i>Ailments</i>
CSF, blood, stool, and respiratory	Meningitis/meningoencephalitis
CSF, blood, stool, and respiratory	Neonatal sepsis
CSF, blood, stool, and respiratory	Acute flaccid paralysis/myelitis
Vesicle fluid, respiratory and stool	HFMD/other rash
Respiratory and stool	Respiratory diseases
Stool, respiratory, blood or heart biopsy	Myocarditis
Eye swab	Conjunctivitis

CSF = cerebral spinal fluid, HFMD = hand, foot and mouth diseases.

extracted RNA. Although the molecular methods accurate, sensitive and fast but some of the EVs such EV-D68, EV-C15 and EV-109 could not be detected by these methods (Piralla et al., 2013; Jaramillo-Gutierrez et al., 2013; Dunn et al., 2015). Nowadays various real time commercial RT-PCRs are available to detect EVs and additional facts are needed to authenticate the accuracy of the commercially available assay for the detection of EVs with different 5'-NCR sequences (Piralla et al., 2013; Jaramillo-Gutierrez et al., 2013; Dunn et al., 2015). It has been found that PCR of fecal specimens is unsuccessful because different substances are present that hinder the step of polymerization.

Cell culture

Cell culture is no longer used for the diagnosis of EVs and it can be used for the authentication of PCR-negative specimens in case of the new variant, more than one viral strain in specimen detection. The collection of specimens, preparation of sample and methodology in virus isolation can be seen in the WHO guidelines (World Health Organization, 2004; Chen et al., 2014). EVs different strains can be isolated in cell cultures of mammalian cell lines and some other cell lines including monkey kidney cells, human fibroblasts (World Health Organization, 2004; Schmidt et al., 1975). The cell culture from CSF, pericardial fluid, tissue, blood or stool can be used to isolate EVs. The CPEs were found to be in 2–5 days in cell culture after inoculation. After isolation of EVs, the serotype is identified for EVs using RNA sequencing. It has been found that EV 71 is poorly grown on cell cultures (Jaramillo-Gutierrez et al., 2013) whereas EVD68 required lower incubation temperature than normally used for EVs (Zaidi et al., 2016).

Serology

Serological methods (i.e., ELISA, neutralization tests) are not used for the confirmation of acute EV infections. Specific antibodies (i.e., IgG, IgM) assay for the detection of EVs infections are present but their clinical utility is limited because of cross reactivity of the antigens between distinct serotypes. The serological tests are time consuming (2 weeks) and which makes diagnosis slow and clinically irrelevant. In the case of myocarditis and pericarditis or cardiomyopathy serological testing is preferred because direct sampling is not possible so, therefore, antibody detection could be useful for diagnostic purposes. The quantification of neutralizing antibodies testing against selected EVs can be used (Nijhuis et al., 2002).

Diseases caused by EVs

The most recurrent complications of EVs infections are the involvement central nervous system (CNS) (Moore, 1982; Jubelt and Lipton, 2014). The CNS disease syndromes caused by EVs are diverse and each syndrome could be caused by various strains of EVs. The neurological disorders caused by specific strains of EVs are listed in Table 14. EVs associated CNS disease syndromes are discussed below.

Aseptic meningitis (AM)

The most common neurological disorder caused by EVs is aseptic meningitis (AM) (Grist et al., 1978; CDC, 1981; Moore, 1982). However, EVs also cause viral meningitis (VM) (Chonmaitree et al., 1982a, b; Pönkä and Pettersson, 1982; Nicolosi et al., 1986; Kupila et al., 2006). Previously it was believed that AM is a type of nonparalytic poliomyelitis but the majority of the cases are caused by nonpolio EVs (Johnson et al., 1960). Centers of Diseases Control (CDC) gives a surveillance report on AM in 1976 which shows that around 83% of cases are of viral meningitis (CDC, 1979). The primary causative viruses for AM are coxsackievirus, echovirus and EV 71 (Schmidt et al., 1974a, b; Grist et al., 1978; Lerner et al., 1978; Singer et al., 1980; CDC, 1981; Chonmaitree et al., 1981a, b, 1982a, b; Thivierge and Delage, 1982; Moore et al., 1983; Morens et al., 1991; CDCP, 2010; Jeong et al., 2010). The major symptoms associated with AM are fever, headache, meningeal signs, CSF pleocytosis, and sterile bacteriologic cultures. VM is the most common AM and there is an inflammatory reaction in meninges which is due to the replication of the virus in meningeal and ependymal cells. VM results in the nonspecific flu like illness that consists of various symptoms including low grade fever, sore throat, malaise, anorexia, nausea, vomiting, diarrhea, headache and photophobia. Also, there are some specific nonneurological

Table 14 Neurological disorders caused by EVs (Jubelt and Lipton, 2014).

<i>Virus strain</i>	<i>Disorder</i>
PV (1–3), Coxsackieviruses (A1–11, 14, 16–18, 22, 24, B1–6), Echoviruses (1–7, 9, 11–21, 24, 25, 27, 29–33), Enterovirus (EV 71), Parechoviruses (1,2)	Aseptic meningitis
PV (1–3), Coxsackieviruses (A2, 4–9, B1–6), Echoviruses (2–4, 6, 7, 9, 11, 14, 17–19, 25), Enterovirus (EV 71)	Encephalitis
Coxsackieviruses (A16, B1), Enterovirus (EV 71), Echoviruses	Rhombencephalitis/ Brainstem
PV (1–3), Coxsackieviruses (A2–4, 6–11, 14, 16, 21, B1–6), Echoviruses (1–4, 6, 7, 9, 11, 13, 14, 16, 18–20, 30, 31)	Paralytic disease
Enterovirus (EV 70, 71), PV (1,3), Coxsackieviruses (A2, 4, 7, 9, B1–6)	Acute cerebellar ataxia
PV (1–3), Coxsackieviruses (A10, 85), Echovirus (4), Enterovirus (EV 70)	Isolated cranial nerve palsies
PV (1–3), Coxsackieviruses (A15, B3), Echoviruses (2, 3, 5, 7, 9, 11, 15, 17–19, 22, 24, 25, 27, 29, 30, 33)	Chronic infections

syndromes including rashes, pleurodynia or pericarditis that may occur. The fever usually ranges from 38 °C to 40 °C and the meningeal symptoms may vary from neck pain, stiffness to severe nuchal rigidity. The symptoms for AM resolves in 1 week but malaise and fatigue may remain for various weeks. Some bacterial, fungal and parasitic infections may also include in the differential diagnosis of EV meningitis (Klawans and Goetz, 1978). The viruses (i.e., herpes simplex, arboviruses (toga- and bunyaviruses), lymphocytic choriomeningitis) which are causing childhood infections may also cause AM (CDC, 1979; Beghi et al., 1984; Jubelt, 2010a). Sarcoidosis and meningeal carcinomatosis are noninfectious causes that should also be taken into consideration for the diagnosis of AM. Nonviral infectious diseases could also present clinically as meningitis that is associated with a CSF mononuclear pleocytosis. The nonviral infections include less invasive or subacute bacterial infections (i.e., brucellosis, mycoplasma, listeria), bacterial meningitis, parameningeal infections, leptospirosis, secondary syphilis, Lyme disease, tuberculosis (TB), rickettsial infections, fungal meningitis (i.e., cryptococcosis, candidiasis, coccidioidomycosis) and parasitic infections (i.e., cysticercosis, angiostrongylus eosinophilic meningitis) (Editorial, 1978; Johnson, 1998; Jubelt, 2010b, c). The development of these nonviral infections results in the decrease of CSF glucose that helps in the clarification of the diagnosis and this differential diagnosis can be combined with stains, cultures and nucleic acid amplification of the CSF to ensure the disease and causative agent (Lee and Davies, 2007; Archimbaud et al., 2009). Noninfection diseases such as carcinomatous meningitis, collagen vascular meningitis and sarcoidosis could also be present as AM (Johnson, 1998).

Encephalitis

The second most common neurological disease caused by EVs is encephalitis (CDC, 1981; Yang et al., 2005). During the outbreak of EVs infection, it has been found that every fourth case of encephalitis of known cause (CDC, 1982; Frantzidou et al., 2008). The causative agents of encephalitis are coxsackieviruses, echoviruses and EV 71 (Horstmann and Yamada, 1968; Grist et al., 1978). The word encephalitis is used when there is a clinical proof of the involvement of the brain. In EV encephalitis there is a direct invasion of the virus. This invasion results in the damage of parenchyma along with neurons cytolytic infection and is called primary encephalitis. Secondary encephalitis is postinfectious encephalomyelitis and it is the immune mediated process. There is the involvement of meninges in the patients of encephalitis so, therefore, the accurate term to used is meningoencephalitis. There are symptoms of AM (i.e., fever, headache, nuchal rigidity) with proof of the involvement of parenchymal cells. This proof of the involvement of parenchymal cells includes the seizures, focal neurologic signs and alteration of mental status (Howe and Wilson, 1959; Melnick, 1965; Horstmann and Yamada, 1968; Grist et al., 1978; Morens et al., 1991). The changes in mental status are of mild type but strange behavior or coma could occur (Sells et al., 1975; Acharya et al., 2001; Cree et al., 2003). The clinical manifestations occur during EV encephalitis are mild and transient, therefore, it is mild with good recovery.

EV encephalitis differential diagnosis includes various similar viruses that are causative agents for AM (i.e., measles, mumps, varicella, rubella), arboviruses (i.e., toga- and bunya-viruses), and herpes simplex) and other viruses (i.e., adenovirus, cytomegalovirus, Epstein-Barr virus, herpes zoster) (CDC, 1979; Koskiniemi and Vaheri, 1982; Beghi et al., 1984). Various nonviral infections such as mycoplasma, legionnaire's diseases, Lyme disease, leptospirosis, syphilis, brucellosis, subacute bacterial endocarditis, brain abscess Rocky Mountain spotted fever, toxoplasmosis, cysticercosis, amebiasis, schistosomiasis, cysticercosis, amebiasis, schistosomiasis, malaria, trypanosomiasis echinococcus and trichinosis are also included in the differential diagnosis of encephalitis (Ho, 2000; Johnson, 1998; Jubelt, 2010a, b, c). Vasculitis, sarcoid and gliomatosis are noninfectious diseases that have to be considered in the differential diagnosis of encephalitis (Johnson, 1998). EV 71 is a causative agent of rhombencephalitis/brainstem encephalitis in the pandemic of HFMD in the Asia Pacific region for the last 15 years. It has been found that when polioviruses cause encephalitis it involves the brainstem with the reticular formation damage including bulbar polio as compared to that of the cortex (Baker, 1949; Howe and Wilson, 1959; Plum and Swanson, 1959). In the majority of bulbar poliomyelitis cases extremity paralysis has also been found to occur. Few other cases of brainstem encephalitis are caused by echovirus, coxsackieviruses A16 and B1 (Kuntzer et al., 1987; Goto et al., 2009; Brecht et al., 2010).

Paralytic disease

Poliomyelitis is rare in the developed countries with the development of killed (1955) and live vaccines (1961) (Paul, 1971a, b; CDC, 1981). 118 cases of paralytic poliomyelitis have been reported in 1975–1984 and these cases were majorly caused by live vaccines (CDC, 1986a, b; Nkowane et al., 1987). Poliomyelitis is derived from Greek words polios (gray) and myelon (marrow). It is caused by poliovirus that infects anterior horn motor neurons of the spinal cord gray matter. During the preparalytic period (24–48 h) before paralysis, there is the onset of minor illness including fever, headache, nausea, vomiting, malaise and sore throat. The major illness during poliomyelitis comprises of all CNS diseases [i.e., nonparalytic polio, aseptic meningitis (AM), polioencephalitis, bulbar polio, paralytic poliomyelitis] caused by the poliovirus. Before paralysis, polioencephalitis along with tremulousness, agitation and upper motor neuron (UMN) signs (i.e., hyperactive deep tendon reflexes, spasticity, Babinski signs) (Jubelt and Cashman, 1987) may also present. Radicular pain, muscle pain, cramping and fasciculation also occur before the onset of paralysis (Morens et al., 1991; Melnick and Ledinko, 1953; Horstmann, 1963).

Spinal poliomyelitis is more common than the involvement of the brainstem and it has been found that the lumbar region is often more affected than the cervical region. Therefore, the paralysis is asymmetric, flaccid, more proximal than distal and spotty (Howe and Wilson, 1959). It accounts for around 5% of clinical infections and 0.1–2.0% of enterovirus infections (Melnick and Ledinko, 1953; Horstmann, 1963). Paralysis leads to bulbar involvement along with weakening respiration and spinal poliomyelitis may often cause autonomic dysfunction (i.e., hyper or hypohidrosis, low limb temperature), urinary retention, sensory

complaints and rare sensory signs (Plum, 1956; Howe and Wilson, 1959). It has been found that in children bulbar polio without paralysis is more common, however, in adult's bulbar involvement with limb paralysis also present. Cranial nerves i.e., 7, 9, 10th are affected which results in facial weakness and difficulty in swallowing.

There are 10–15% paralytic cases of bulbar poliomyelitis (Howe and Wilson, 1959) and it involves the cranial nerves and the medullary reticular formation (Peart, 1949; Olin, 1952; Weinstein, 1957). Bulbar poliomyelitis is more common in children without paralysis of a limb, however, there may be paralysis of a limb. The common affected cranial nerves are 7, 9 and 10th which lead to facial weakness and difficulty in swallowing (Aycok, 1942; Anderson and Rondeau, 1954; Ogra, 1971). The 5 and 12th cranial nerves are less commonly affected which results in the weakness of muscles of mastication and tongue. The formation of reticular may results in irregularities in breathing, swallowing and cardiovascular system (i.e., hypertension, hypotension, cardiac arrhythmias, etc.) (Levinson et al., 1945; Russell, 1949; Hill and Knowelden, 1950; Horstmann, 1950; Ben-Efraim and Long, 1957; Guyer et al., 1980; Jubelt and Lipton, 2014).

Nonpolio EV has also been found to cause paralytic disease, however, it is not common. In the year from 1976 to 1979, 52 cases of paralytic disease caused by EV in the USA, 25 cases were caused by PV, 18 by echoviruses, 7 by coxsackieviruses and 2 by EV 71 (CDC, 1981). Coxsackievirus, echovirus, EV 70 and 71 are the causative agents of paralytic disease. EV 70 was the causative agent of the acute hemorrhagic conjunctivitis (AHC) epidemic throughout the world. AHC first occur in Asia and Africa but afterward spread to Latin America and the USA (Patriarca et al., 1983). It has been found that in 10,000–15,000 cases there is one case of AHC complicated by neurological disorder (Hung and Kono, 1979; Wadia et al., 1983a, b). The paralytic disorder caused by EV 70 was referred to as radiculomyelitis because of the pain and paresthesias (Hung et al., 1976; Hung and Kono, 1979; Katiyar et al., 1983; Wadia et al., 1983a, b; Vejajiva, 1989). EV 71 was isolated in the USA (1969) is associated with HFMD and AM (Schmidt et al., 1974a, b; Deibel et al., 1975). A severe epidemic caused by EV 71 in Bulgaria and this infection is characterized by poliomyelitis like paralytic disease (Melnick et al., 1979). All EVs should be included in the differential diagnosis of paralytic disease and various other viruses (i.e., rabies, herpes zoster, West Nile virus, flaviviruses, etc.) could also cause acute lower motor neuron paralysis (Thomas and Howard, 1972; Chopra et al., 1980; Jeha et al., 2003).

Cranial nerve palsies

It has been found that cranial nerve palsies (CNP) are part of bulbar poliomyelitis and the CNP always occurs with EV infections. EV 70 has been found to cause CNP along with neurological complications and the patients have also been found to possess limb paralysis (Katiyar et al., 1983; Wadia et al., 1983a, b). It has been found that one fourth of patients have isolated CNP with neurological involvement but in some epidemics, the percentage of isolated CNP is very low (Hung and Kono, 1979; Katiyar et al., 1983; Wadia et al., 1983a, b). Patients suffering from isolated CNP have been found to affect the facial nerve accompanied by motor trigeminal nerve. Cranial nerves such as 2, 3, 4, 6, 8, 9, 10, 11 and 12th are affected in isolated CNP and isolated facial nerve palsies have been found to occur after poliovirus, coxsackievirus and echovirus infections (Weiner, 1978). Rhombencephalitis caused by EV 71 shows the involvement of cranial nerves and the most commonly involved cranial nerves are 3, 4, 6, 7, 9, 10 and 12th (Huang et al., 1999; Ooi et al., 2010).

Acknowledgments

The author is very grateful to Mr. and Mrs. Muhammad Anwar and Iqbal Ahmad for their valuable guidance and support.

Introduction

The *Caliciviridae* family is composed of small non-enveloped icosahedral, positive-sense RNA viruses that infect a wide range of vertebrates including mammals, birds, and fish (Vinjé et al., 2019); moreover, some unclassified caliciviruses have been detected in reptiles and amphibians (Sandoval-Jaime et al., 2012; Smith et al., 1986). Caliciviruses, classified in 11 genera, cause a broad range of species-specific gastrointestinal, respiratory, vesicular, and severe systemic infections.

The majority of the members of this family do not replicate well in cell culture systems, which has caused lags in the knowledge of its life cycle; however, their biology and pathogenesis have been mostly studied using the cultivable Feline calicivirus (FCV) and murine norovirus (MNV) models, and some of the developed reverse genetic approaches. The present chapter aims to provide an overview of the members of the *Caliciviridae*, including animal and human genera.

Taxonomy

The first report of a calicivirus was published in 1957 (Fastier, 1957) when FCV was isolated using tissue cultures, although it was initially classified as a feline picornavirus. Its structure was later defined by transmission electron microscopy (Peterson and Studdert, 1970). However, the first calicivirus identified was Norwalk virus (NV), a human norovirus (HuNoV) first isolated in 1968 from a human stool sample and reported in 1972 as a causative agent of gastroenteritis.

Today, we know that caliciviruses infect a wide variety of vertebrates from fish to humans, causing diverse pathologies. Of the 11 genera that conform the *Caliciviridae* family, the first well established genera were *Norovirus* and *Sapovirus* that contain viruses that infect humans, known as Human caliciviruses (HuCVs); other genera are *Vesivirus*, associated with respiratory and vesicular diseases in wild and domestic cats, as well as vesicular exanthema in swine (Edwards et al., 1987); *Lagovirus* that cause hemorrhagic diseases in lagomorphs such as rabbits and hare (Mahar et al., 2019) and *Nebovirus* that cause gastroenteritis in cattle. The six additional genera recently accepted, were named *Bavovirus*, *Minovirus*, *Nacovirus*, *Recovirus*, *Salovirus*, and *Valovirus* (Vinje et al., 2019) (Table 1). Most of these novel caliciviruses were identified and isolated from poultry and fish farming specimens, but few studies have been done searching for caliciviruses in wild animals (Sandoval-Jaime et al., 2012; Smith et al., 1986), suggesting that there are more possible genera to be discovered and described.

Study of the biology of these novel caliciviruses can have a positive impact in the farming industry, as specific diagnosis protocols, antiviral treatments and/or vaccines can reduce morbidity and mortality in livestock and the subsequent economic losses

Table 1 Representative members of the *Caliciviridae* genera.

Genus	Representative virus	Natural host	Pathology	References
<i>Bavovirus</i>	Bavaria virus	Chicken	Possibly diarrheal disease	Wolf et al. (2011)
<i>Lagovirus</i>	Rabbit hemorrhagic disease virus	Rabbit	Highly lethal liver infection	Liu (1984)
<i>Minovirus</i>	Fathead minnow calicivirus	Fathead minnow	Possible hemorrhage in skin, fin bases and eyes	Mor et al. (2017)
<i>Nacovirus</i>	Turkey calicivirus	Turkey	Gastroenteritis	Wolf et al. (2012)
<i>Nebovirus</i>	Newbury-1 virus	Bovine	Gastrointestinal infection	Kapikian et al. (1972) and Oliver et al. (2006)
<i>Norovirus</i>	Human norovirus, Murine norovirus	Humans, Mouse	Gastrointestinal infection	Karst et al. (2003)
<i>Recovirus</i>	Tulane virus	Rhesus monkeys	Gastrointestinal infection	Smiley et al. (2002)
<i>Salovirus</i>	Atlantic salmon calicivirus	Atlantic salmon	Possible heart and skeletal muscle inflammation	Mikalsen et al. (2014)
<i>Sapovirus</i>	Porcine sapovirus, Human sapovirus	Pigs	Gastrointestinal infection	Guo et al. (2001)
<i>Valovirus</i>	St-Valérien-like virus	Pigs	Apparent asymptomatic	L'Homme et al. (2009)
<i>Vesivirus</i>	Feline calicivirus	Household cat	Upper respiratory system infection/Systemic infection by some strains	Fastier (1957)

and zoonotic risks; moreover, characterization of new caliciviruses can provide new information of their biology and possible new study models to understand HuNoV infection.

For *Norovirus* classification, there are 2 different, complementary systems based on VP1 amino acid or RNA dependent RNA polymerase (RdRp) nucleotide sequences that result in the genogroups and genotypes or P-groups and P-types, respectively. To these days, there are 49 genotypes belonging to 10 genogroups (GI-X) and 60 accepted P-types. Future norovirus nomenclature updates will require the full genome sequences to determine both genotype and P-type (Chhabra et al., 2019).

Molecular biology

Capsid and genome

The *Caliciviridae* family is composed of non-enveloped icosahedral viruses from 27 to 40 nm in diameter. Their capsids consist of 180 copies of the major structural protein VP1 arranged in dimers that form an icosahedral $T = 3$ shell (Prasad et al., 1999; Venkataram Prasad et al., 2000). When expressed in in vitro systems, this protein spontaneously assembles into virus-like particles; however, co-expression with the minor structural protein VP2 has demonstrated that this protein interacts with VP1 for the formation of the viral capsids (Di Martino et al., 2007).

Caliciviruses have a single-stranded and positive-sense genomic RNA (gRNA) of 6.4–8.5 kilobases (Kb) in length, which is covalently linked to the viral genome-linked protein (VPg) to its 5' end; the genome at its 3' end is polyadenylated.

The viral genomes are organized in either two or three open reading frames (ORF) depending on the genus. The non-structural (NS) proteins are always encoded from the first ORF; while the major VP1 and minor VP2 structural proteins from the members of the *Vesivirus*, *Norovirus*, and *Recovirus* genus are encoded from the second and third ORFs; in the members of the *Bavovirus*, *Lagovirus*, *Minovirus*, *Nacovirus*, *Nebovirus*, *Salovirus*, *Sapovirus*, and *Valovirus* genus, VP1 is encoded in-frame and contiguous with the NS proteins, and VP2 is encoded from the second ORF (Vinjé et al., 2019). Particularly in the members of the *Vesivirus* genus, the second ORF encodes the precursor of the VP1 protein that is further cleaved into the mature VP1 and a smaller protein, named leader of the capsid (LC) that is cytopathic and responsible for the induction of apoptosis (Abente et al., 2013; Barrera-Vazquez et al., 2019). A fourth ORF has been reported in the murine norovirus (MNV), a member of the *Norovirus* genus, that encodes for the virulence factor-1 (VF-1) (McFadden et al., 2011); moreover, an equivalent fourth ORF is present in human sapoviruses, although the encoded proteins are yet of unknown function (Chanit et al., 2009) (Fig. 1).

Besides the gRNA, a 5'-end VPg-linked and polyadenylated subgenomic RNA (sgRNA) containing the second and third ORFs is synthesized late in infection and drives the production of VP1 and VP2 structural proteins. However, evidence has published indicating that VP1 can also be produced from the genomic RNA at early times of the viral replication cycle even when the VP1 encoding region is not in the ORF1, as in *Norovirus* and *Vesivirus* (McCormick et al., 2008; Urban and Luttermann, 2020).

The encapsidation of the gRNA and the sgRNA has been documented during RHDV infection (Meyers et al., 1991).

Genomic RNAs

Fig. 1 Calicivirus genome organization. Schematic representation of the genomic organization in the different genera of the *Caliciviridae*. Both the genomic and subgenomic RNAs have the Vpg protein covalently-linked to the 5' ends and are polyadenylated at their 3' ends. Depending on the genus, the genome contains from 2 and up to 4 ORFs flanked by short untranslated regions (blue lines). ORF1 always encodes for a polypeptide that is cleaved into six non-structural (NS) proteins, and in some genus, for the VP1 protein. ORF2 and ORF3 encode for the major and minor structural VP1 and VP2 proteins from the sgRNAs, respectively. A fourth ORF is contained only in the MNV genome and encodes for the VF1 protein from the sgRNA. The members of the *Vesivirus* genus encodes for a precursor of the VP1 protein that is further cleaved to produce the leader of the capsid (LC), and the mature VP1 proteins.

Calicivirus replication cycle

Early events: Binding, entry, and uncoating

The viral replication cycle of caliciviruses, start with the interaction of the viral particle to attachment/binding and entry factors; many of them carbohydrate ligands, glycolipids, and proteins present in the surface of the cell (reviewed in: [Graziano et al., 2019](#)) (see “Calicivirus receptors” section).

Following binding to the cell surface receptors, caliciviruses entry into the cells is mediated by endocytic pathways. FCV entry is both clathrin-dependent and pH-dependent, as capsid uncoating and genome release into the cytoplasm requires the acidic environment of the endosome; in contrast, MNV entry is dependent on cholesterol and dynamin and was reported to be pH-independent ([Gerondopoulos et al., 2010](#); [Perry et al., 2009](#)). Recently, endosomal acidification and cathepsin L activity were reported to be required for FCV, porcine enteric calicivirus (PEC) and MNV entry events ([Shivanna et al., 2014b](#)). If the differences in the endocytic pathway are virus-specific, host species-specific or cell type-specific is still unknown ([Graziano et al., 2019](#)).

Endosomal escape and viral uncoating end in the release of the viral genome into the cytoplasm, a process poorly understood for the *Caliciviridae* members; however, a mechanism of FCV genome release has been recently described ([Conley et al., 2019](#)). The minor FCV capsid protein VP2 forms a portal-like assembly at a threefold axis of symmetry after the feline junctional adhesion molecule (fJAM-1) receptor engagement. This assembly is formed of 12 copies of VP2 arranged with their hydrophobic N termini pointing away from the virion surface, leading to the opening of a pore in the capsid shell that presumably acts as a channel for the delivery of the genome into the cytoplasm ([Conley et al., 2019](#)).

Genome translation and replication

Once the calicivirus genome reaches the cell cytoplasm, the synthesis of a large polyprotein occurs by a VPg-mediated translation initiation process. Both canonical eukaryotic initiation of translation factors (eIFs), as well as non-canonical factors, participate in the initiation and regulation of translation ([Chaudhry et al., 2006](#); [Daughenbaugh et al., 2003, 2006](#); [Goodfellow, 2011](#); [Goodfellow et al., 2005a](#); [Gutierrez-Escolano, 2014](#); [Hernandez et al., 2016](#); [Hosmillo et al., 2014](#); [Karakasiliotis et al., 2010](#)).

The polyprotein is further processed by the only viral protease to produce 6 NS proteins: NS1/2, the helicase NS3, NS4, and NS5 or VPg, and the protease NS6 and the RNA dependent RNA polymerase (RdRp) NS7. Particularly, during *Vesivirus* infection, NS1 and NS2 are excised as separated proteins, while NS6/7 the protease-polymerase does not undergo additional processing ([Sosnovtsev et al., 2002](#)); in the case of the other caliciviruses, NS6 and NS7 are fully processed into independent proteins ([Emmott et al., 2019](#); [Oka et al., 2005](#); [Sosnovtsev et al., 2002, 2006](#)). The function of the NS proteins is partially conserved in the *Caliciviridae* family with, some proteins having a main described function and other possible roles in achieving efficient viral replication (Fig. 2).

Fig. 2 Calicivirus replication cycle. The viral replication cycle starts with the binding of the viral particles to the cell surface. After the interaction with the cell receptor, the viral particles enter the cells through an endocytic pathway, followed by the genome release into the cytoplasm. Vpg mediated translation of the genomic RNA (gRNA) occurs to produce a polyprotein, which is further cleaved by the viral protease into the individual non-structural (NS) protein. The NS proteins drive the formation of membrane-delimited replication compartments (RC) where the negative sense (–) RNAs are synthesized from the gRNA. The (–) RNAs serve as a template for the synthesis of the sgRNAs and the viral progeny genomes. sgRNAs are immediately translated to produce the structural proteins that auto-assemble together with the gRNAs (encapsidation). Apoptosis induction promotes viral particles dissemination through the host. gRNA (genomic RNA); (–) RNA (negative-sense RNA); sgRNA (subgenomic RNA); RF (replicative forms); NS (non-structural proteins).

Non-structural proteins

NS1/NS2 proteins are fused in *Recovirus* and *Norovirus* genera, and have a viroporin function; the expression of NS1/2 interrupts Ca^{2+} homeostasis in TV and potentiates apoptosis and virus persistence in MNV infection (Nice et al., 2013; Robinson et al., 2019). NV NS1/2 transient expression in cells is involved in the Golgi complex disassembly and membrane rearrangement needed for the replication complexes (RC) formation (Doerflinger et al., 2017; Fernandez-Vega et al., 2004). This Golgi membrane disruption most probably occurs by the interaction of NS1/2 with vesicle-associated membrane protein-associated proteins (VAPs), as demonstrated during NV and MNV infection, resulting in the alteration of vesicular trafficking (Ettayebi and Hardy, 2003; McCune et al., 2017).

On the other hand, during FCV infection, NS2 (p32) is cleaved by the viral protease from NS1 (p5.6), producing two proteins of 32 and 5.6 kDa, respectively. While not much is known about NS1 function, NS2 is involved in membrane alteration and likely in the RC formation, as in NV and MNV infection (McCune et al., 2017).

NS3 is a conserved protein among caliciviruses whose main function is an NTPase- and RNA chaperone that uses Mg^{2+} as a cofactor. NS3 from MNV has an additional helicase activity (Han et al., 2018), whereas in other noroviruses such as the GI HuNoV Southampton, this helicase activity was not detected (Pfister and Wimmer, 2001). The HuNoV GII.4 NTPase has mitochondrial localization due to its C-terminal domain and possesses pro-apoptotic activity. NS3 from FCV, NV, and MNV induces membrane rearrangements (Cotton et al., 2017; Doerflinger et al., 2017); moreover, in both FCV and MNV infection, NS3 impairs the host immune response (Fritzlar et al., 2018; Yumiketa et al., 2016).

NS4, a protein between 22 and 32 kDa, is not highly conserved among caliciviruses, except for a conserved predicted transmembrane domain. This protein has different function(s) in distinct viral genera; NS4 from FCV (p30) and NV (p22) induces membrane rearrangements, (Bailey et al., 2010; Doerflinger et al., 2017) while NS4 (p22) from HuNoV and MNV hamper the cellular secretory pathway (Sharp et al., 2012) likely interrupting the COPII-coated vesicle trafficking that results in the Golgi apparatus disassembly (Sharp et al., 2010). Inhibition of protein secretory pathway or Golgi disruption is not induced by FCV NS4, suggesting that these are only conserved functions among noroviruses.

NS5, also known as VPg (for virion protein, genome-linked), is the genome-linked protein to the 5' of the viral genomic and sgRNAs (Goodfellow et al., 2005b). Its main described function is the recruitment and assembly of the host translation machinery, working as a proteinaceous cap that promotes calicivirus translation. The differential interactions of canonical translation factors with VPg have been demonstrated in *Norovirus* (Chung et al., 2014; Daughenbaugh et al., 2006; Leen et al., 2016) *Vesivirus*, (Goodfellow et al., 2005a), *Sapovirus* (Hosmillo et al., 2014) and *Lagovirus* genera (Chaudhry et al., 2006; Zhu et al., 2015).

Besides participating in calicivirus genome translation, HuNoV VPg has a role in the RNA replication; VPg is nucleotidylated in its tyrosine 27 residue by the action of the RdRp or its precursor, priming the replication of gRNA (Belliot et al., 2008; Rohayem et al., 2006). Nucleotidylation seems to be dependent on NTP binding, appears to be more efficient when the immature protease-polymerase interacts with VPg and involves a 3' unidentified element (Medvedev et al., 2017).

Another reported function of VPg is the cell cycle arrest leading the cells to a G0/G1 stage through its N-terminal domain (Davies and Ward, 2016); this function seems to be both independent of its role in RNA translation and replication and conserved in distinct calicivirus genera (McSweeney et al., 2019). Since this protein is also found in virus particles attached to the genome, it has been suggested to be categorized as a structural protein (Smertina et al., 2019).

The NS6 protein is the only protease codified by caliciviruses. It is also known as the 3C-like proteinase because of the similarity found with the picornaviral 3C protease when it was first characterized. This viral protease has conserved catalytic residues (Oka et al., 2007), and is responsible for the processing of the viral polyprotein into the different mature NS proteins (Liu et al., 1996; Oka et al., 2005; Sosnovtsev et al., 2006; Würblich et al., 1995). In vesiviruses like FCV, where the NS6/7 proteins are fused (Wei et al., 2001), this protease-polymerase also cleaves its capsid protein precursor (Sosnovtsev et al., 1998). The proteolytic processing of the NS proteins follows a particular order determined by the protease enzyme affinity to its cleavage sites (Emmott et al., 2019; May et al., 2014). The structure of the protease NS6 from distinct caliciviruses has been determined, providing insight on 3D conformation of both protease and protease-substrate protein complex, with possible treatment implications (Galasiti Kankana-malage et al., 2015; Leen et al., 2012; Nakamura et al., 2005).

Besides cleaving the viral polyprotein for the generation of the mature NS proteins, the calicivirus proteases cleave cellular proteins to favor the establishment of the infection (Emmott et al., 2017; Kuyumcu-Martinez et al., 2004). For example, FCV NS6/7 protein induces cellular transcription shutoff through its N-terminal domain (Wu et al., 2016), while RHDV NS6 protein induces apoptosis (Chen et al., 2018).

NS7 is the conserved RdRp, involved in the production of all the viral RNAs, such as the negative-sensed RNA replication intermediate, as well as the genomic and the sgRNAs from which the structural proteins VP1 and VP2 are synthesized to encapsidate the genomes of the viral progeny. The initiation of RNA synthesis is dependent on NS7 nucleotidylation of VPg, as mentioned above. The low fidelity of the RdRp may contribute to viral transmission efficiency through an increased genetic diversity (Arias et al., 2016), and it is known that GII HuNoVs RdRp is phosphorylated by the Akt cellular kinase (Eden et al., 2011) and in general, it is known that NS7 proteins from diverse calicivirus form a multiproteic complex with viral and cellular proteins that have a role in viral replication cycle (Cancio-Lonches et al., 2011; Santos-Valencia et al., 2019; Vashist et al., 2015). In RHDV, the NS7 protein uniquely induces the rearrangement of Golgi apparatus membranes (Urakova et al., 2017a) through a partially hidden hydrophobic motif (Urakova et al., 2017b) independent of its polymerase function, possibly contributing to the RC complexes formation. The structural dynamics, biochemical properties, kinetics, and putative interaction partners of the calicivirus RdRps has been recently reviewed (Smertina et al., 2019).

In addition to the role of NS proteins in the RNA translation and replication, several cellular proteins, also known as non-canonical factors, participate in regulating calicivirus replication. The polypyrimidine tract binding protein binds to the 5' end of the FCV genome and functions as a negative regulator of its translation most probably to promote the synthesis of viral RNA (Karakasiliotis et al., 2010). Moreover, nucleolin (NCL) has been reported to bind to the NV and FCV 3' untranslated regions and is most probably part of the FCV translational complex; its N-terminal region is required for an efficient FCV replication (Cancio-Lonches et al., 2011; Hernandez et al., 2016). On the other hand, the poly C binding protein (PCBP)-2 and the heterogeneous nuclear ribonucleoprotein (hnRNP)-A1, bind to the 5' and the 3' ends of the MNV-1 viral RNA and contribute to RNA circularization, playing a role in the virus replicative cycle (López-Manriquez et al., 2013).

The production of the NS proteins contribute in the formation of the replicative complexes (RC), membrane-delimited compartments derived mostly from the Golgi apparatus and the Endoplasmic Reticulum (ER) (reviewed in Penaflor-Tellez et al., 2019), where the synthesis of the genomic and subgenomic RNAs through the production of a negative-sense RNA template occur by the action of the RdRp (Smertina et al., 2019).

While the major function of the gRNAs is to form the genomes of the viral progeny, the sgRNAs are immediately translated to produce the structural proteins VP1 and VP2.

Structural proteins

VP1, known as the major viral protein, is a 58–60 kDa protein divided into three domains: the N-terminal arm (NTA) domain, the highly conserved shell (S) domain that consists of an eight-chain anti-parallel β -sandwich with two α -helical decorations, and the protruding (P) domain. The NTA and S domains are located in the inner surface of the capsid that surrounds the viral RNA. The P domain can be divided into two subdomains (Choi et al., 2008); the P1 subdomain that consists of a single α -helix and eight β -strands and is connected to the S domain by a flexible stem-like hinge, and the P2 subdomain that appears as an insert in P1 (137 amino acids, 278–415) that forms a six-chain anti-parallel β -type antiparallel structure. The P2 subdomain interacts with its respective cell receptor and it is a target for neutralizing antibodies (Choi et al., 2008). The minor capsid protein VP2 is a 8–12.2 kDa basic protein, highly variable in sequence between genera, that is essential for virus infectivity and is incorporated into the virion at a low copy-number providing capsid stability (Bertolotti-Ciarlet et al., 2003; Sosnovtsev et al., 2005) (Fig. 3).

Late steps: Apoptosis induction, encapsidation, and virus release

Increasing evidence indicates that besides their role in the RC formation, viral NS proteins induce intrinsic apoptosis in the infected cells (Chen et al., 2018; Herod et al., 2014; Robinson et al., 2019); a process required for the establishment of a successful infection

Fig. 3 Calicivirus capsid structure. Schematic representation of the *Caliciviridae* capsid structure. Ninety dimers of VP1 make up the viral capsid, which contains the Vpg-linked genomic RNA (Blue). Schematic representation of the VP1 structure: the hypervariable P2 domain (orange) responsible for the interaction with the cell receptor, the conserved P1 domain (yellow) that surrounds the P2 domain, and the S domain or N-terminal region (NTR) (blue-green) located in the inner side of the viral capsid.

also related to immunopathogenesis (reviewed in: [Penaflor-Tellez et al., 2019](#)). Moreover, recent evidence suggests that apoptosis may also participate in the translation suppression of interferon-stimulated genes (ISG) as a mechanism to evade the innate immune response ([Emmott et al., 2017](#)).

Interestingly, the LC protein, unique in the *Vesivirus* genus and produced later in infection as a consequence of the proteolytic processing of the precursor of the capsid protein VP1, appears to be responsible for apoptosis induction in FCV infected cells ([Abente et al., 2013](#); [Barrera-Vazquez et al., 2019](#)). Furthermore, the unique MNV protein VF1 can also modulate apoptosis ([McFadden et al., 2011](#)). These findings correlate with the previous association of apoptosis with the dissemination of the viral progeny in the host ([Alonso et al., 1998](#); [Bok et al., 2009](#)). Thus, once both the mature structural protein VP1 and VP2 are produced, they are immediately self-assembled together with the genomic RNAs to form the infective viral particles, ready to leave after cell lysis the infected cells and propagate into the host. A non-lytic release of human norovirus particles associated with exosomes into stools has been recently reported, representing another mechanism of viral particles liberation that may contribute to person-to-person transmission ([Santiana et al., 2018](#)).

Calicivirus receptors

Viruses to infect must adhere to the cell surface; thus, identify the cellular proteins that serve as viral receptors used by each virus allows to better understand its target cells, the species barriers, the viral entry mechanisms, and thus, the possible key points to block the viral infection.

While some molecules of different origin have been identified to participate in caliciviruses entry, few molecules of protein nature are known to act as their functional receptors.

Histo-blood group antigens (HBGA) are polymorphic carbohydrate structures that represent terminal exposed portions of larger glucans O- or N bound to proteins or glycolipids, that have been widely reported to participate in the cell binding of several members of the family *Caliciviridae*; such as Tulane virus (TV) ([Farkas et al., 2010](#)), Rabbit hemorrhagic disease virus (RHDV) ([Lopes et al., 2018](#); [Nystrom et al., 2011](#)), Canine norovirus (CaNoV), Bovine nebovirus (BNeV) ([Cho et al., 2018](#)) as well as MNV ([Almand et al., 2019](#)) and HuNoV ([Almand et al., 2017](#)). Bile salts such as glycochenodeoxycholic acid (GCDCA) and lithocholic acid (LCA) are also known to interact with the P domain of the VP1 dimer, stabilizing its binding to cellular receptors. Besides GCDCA, divalent cations like calcium and magnesium can also stabilize the binding of VP1 with the MNV CD300lf receptor ([Nelson et al., 2018](#)), and sialic acid participates in MNV ([Taube et al., 2009](#)) and FCV binding ([Stuart and Brown, 2007](#)).

Four proteic molecules have been identified as receptors for five caliciviruses.

1. The feline Junctional adhesion molecule 1 (fJAM-1), an immunoglobulin-like transmembrane glycoprotein of 40 kDa that regulates tight junctions in epithelial and endothelial cells, and also considerably expressed in platelets and to a lesser extent in leukocytes ([Pesavento et al., 2011](#)), is the main receptor for FCV 1. Transfection of fJAM-1 in non-permissive non-lung hamster cells (HmLu-1), led to binding and infection by different strains of FCV ([Makino et al., 2006](#)). The human junctional adhesion molecule 1 (hJAM1) has been described as the human vesivirus Hom-1 functional receptor ([Sosnovtsev et al., 2017](#)). Other junctional molecules such as occludin have been reported to function as a coreceptor for the Porcine sapovirus (PSaV) entry into LLC-PK cells, while claudin-1 facilitates its entry and infection ([Alfajaro et al., 2019](#)),

2. Coxsackievirus and adenovirus receptor (CAR), is an immunoglobulin-like protein (Heath et al., 1997) of 38–40 kDa, located in the tight junctions (Cohen et al., 2001) that participate in neuronal and cardiac physiological processes (Carson et al., 1997; Freimuth et al., 1999; Honda et al., 2000; Nalbantoglu et al., 1999; Shaw et al., 2004). CAR has been found to be the putative receptor for TV and FT285 ReC (Farkas et al., 2019). CAR knockdown, blockage, and knockout induced resistance of LLC-MK2 permissive cells to ReCV infection. In addition to the expression of CAR, HBGA type B expression into the non-permissive CHO cells is required for ReCV infection (Farkas et al., 2019).
3. CD300ld of 22 kDa and CD300lf of 32 kDa belong to the transmembrane glycoproteins CD300 family that contains an extracellular immunoglobulin variable domain (IgV); both molecules have been found to be the main receptors for MNV. Knockdown or blocking the murine CD300lf (mCD300lf) but not the human (hCD300lf), significantly reduced the entry of MNV to the macrophages cell line Raw 264.7. Even though the induction of mCD300ld or mCD300lf expression in human HEK293T cells allowed the infection with MNV (Haga et al., 2016), breaking the norovirus species barrier (Orchard et al., 2016), the huCD300lf is not essential for the entry of HuNoV into human cells (Graziano et al., 2020). Although CD300ld and CD300lf are the main receptors for MNV infection, other proteins have been suggested to participate in MNV entry, such as the cell surface glycoproteins CD44, CD36, CD968, and the transferrin receptor 1 (TfRc) (Bragazzi Cunha and Wobus, 2016). It is of interest that depending on the cell, each of the above molecules can participate in different degrees in the entry of the MNV.
4. Annexin A2 (ANXA2) is a 36 kDa calcium-dependent phospholipid-binding protein, expressed in some tumor cells, endothelial cells, macrophages, and mononuclear cells. ANXA2 has been reported to play roles in exocytosis, endocytosis, and membrane trafficking (Wang and Lin, 2014). ANXA2 was identified as one of five major proteins that bind to rabbit vesivirus (RaV) virions. Knockdown and blockage of ANXA2 in HEK293T cells caused the reduction of RaV infection and areduction of ~1.4 logs in the viral yield, supporting the role of ANXA2 in RaV attachment and/or internalization (Gonzalez-Reyes et al., 2009).

Calicivirus models of study

Surrogate models

Even though NV was identified as the etiological agent of human gastroenteritis outbreaks nearly 50 years ago, one of the main reasons why up to this date we do not know more about certain aspects of the HuNoVs replicative cycle, pathogeny, and the immune response is due to the lack of a convenient *in vitro* or *in vivo* replication model. It is not known why HuNoVs are incapable of effectively replicate in cell cultures or animal models; although, the use of new 3D cell and organoid cultures has provided promising results for its replication (Ettayebi et al., 2016; Papafragkou et al., 2013).

Due to the lack of convenient replication systems for HuNoV, several surrogate models have been developed over the years and became the principal way to study calicivirus biology and pathogenesis. These models, together with reverse genetic systems, are by far the most useful tools to study these viruses and have different advantages in cost-effectiveness and translation of results to the understanding the HuNoV biology.

RHDV, causes highly lethal liver failure, highlighting its importance in the study of veterinary and livestock (reviewed in: Abrantes et al., 2012). To this date, there is no robust cell culture system for its replication; thus, propagation of viral particles has been done through rabbit inoculation and liver tissue preparation (Teixeira et al., 2012). In addition, certain aspects of RHDV replication cycle have been studied with the use of molecular biology tools like replicons, but without obtaining high viral yields (Wang et al., 2013; Zhu et al., 2015). These study techniques have significant limitations, but over time they have been useful tools for the elucidation of crucial aspects of RHDV biology.

PSaV, one of the causative agents of gastroenteritis outbreaks in pigs, was the first surrogate model developed for calicivirus obtained by passages of the Cowden strain through the primary culture of porcine kidney cells supplemented with an intestinal content filtrate preparation from gnotobiotic pigs (Flynn and Saif, 1988). The primary cultures originally used to propagate the Cowden strain were later replaced by the porcine pig kidney continuous cell line LLC-PK. The viral sequence of VP1 and RdRp from viruses grown in LLC-PK showed that mutations accumulated in the VP1 from the viral Cowden strain resulted important for viral replication (Lu et al., 2016). Later, it was determined that bile salts in the intestinal content filtrate was the factor required for viral replication (Chang et al., 2004), likely by activating de cAMP signaling pathway (Chang et al., 2002) and participating in the virus escape from the endosomes (Shivanna et al., 2014a).

Compared to other study models, the Cowden strain of PSaV produced lower viral yields, probably due to an interferon immune response that hampers viral replication (Hosmillo et al., 2015); however, this model has the advantage of having a reverse genetic system, crucial to the study of the role of viral components in the replication cycle (Chang et al., 2005).

From the late 60s and early 70s and up to now, the most popular model to study calicivirus biology was the FCV; key aspects of calicivirus biology were first described in this model, as it replicates successfully in both primary culture epithelial kidney cells (Adldinger et al., 1969; Crandell et al., 1961) and in the Crandell feline kidney (CrFK) permissive cell line (Crandell et al., 1973), where high viral yields were produced. Another added advantage of FCV is that since 1995, several reverse genetic systems have been developed (Oka et al., 2014; Sandoval-Jaime et al., 2015; Sosnovtsev and Green, 1995).

FCV is, without doubt one of the more useful models to understand many aspects of calicivirus biology. Since vesiviruses and noroviruses have similar genome organization, FCV was initially the best reliable model to understand HuNoV infection. However, the discovery of the MNV provided a better model since it has the additional advantages of sharing cell tropism, pathology, and pathogeny with the HuNoVs.

MNV was first identified in 2003 in immunocompromised mice (Karst et al., 2003), and since then it has been established as the most reliable model for studying the molecular biology and pathogenicity of the members of the *Norovirus* genera. MNV ability to replicate in multiple tissue cultures and cell lines (Ward et al., 2006) as well as in healthy or immunocompromised mice has allowed studying norovirus replication cycle, tropism, immune response evasion, and persistence mechanisms. Moreover, several reverse-genetic systems have been rapidly developed to identify the role of MNV proteins in in vitro and in vivo contexts (Arias et al., 2012; Chaudhry et al., 2007; Ward et al., 2007; Yunus et al., 2010).

All these features make MNV, by far, the most currently used model to study *Norovirus* biology; however, the differences between the immune system of mice and humans, the presence of the unique VF1 protein in MNV, the differences in their functional receptor usage, and the fact that even between HuNoVs genotypes there are significant differences in viral protein functions are important factors to consider before assuming that MNV fully mimics HuNoVs replication cycle, pathology, and pathogeny. With this in mind, even though MNV is a powerful and extremely useful tool, the development of a HuNoV replication system is still needed.

The TV, a member of the recent-accepted *Recovirus* genera, is the most recent HuNoV surrogated model, and represent a useful system to study HuNoVs infection (Farkas et al., 2008). As naturally infects Rhesus monkeys, and cause gastrointestinal symptoms, it is strongly pointed out as a better model to study pathology and pathogeny of HuNoV than MNV. Besides infecting Rhesus monkeys, TV can efficiently replicate in the LLC-MK2 monkey kidney cell line. Phylogenetic analysis of TV strains show that recoviruses are the closest genera to noroviruses (Farkas et al., 2008), and a reverse genetic system is available to study specific viral functions (Wei et al., 2008); however, an important disadvantage of this model is the economic cost and bioethics conflicts of using Rhesus macaques as in vivo models.

HuNoVs growth attempts

Throughout the years, several efforts of growing HuNoVs have been made. Since there are no clear clues regarding why some caliciviruses grow efficiently in culture cells while others do not, attempts to establish an effective HuNoVs replication system has been mostly by trial and error and can be broadly categorized into two groups: cell culture approaches to replicate and harvest HuNoV and infection of distinct animal models with HuNoV.

HuNoV growth in cell cultures

Over several decades a wide variety of primary cultures and cell lines were tested for HuNoVs infection (Murakami et al., 2020). Meanwhile, wild type and engineered HuNoVs reverse systems were also developed, aiming to produce infectious viral progeny (Duizer et al., 2004; Lay et al., 2010). The majority of these systems are limited, but some provided information on necessary elements to achieve an efficient viral replication in cell cultures. Two of the most novel approaches are the use of 3D cell and organoid cultures, pointing to recreate the natural niche of HuNoVs infected cells in its natural host. Recreation of villi-containing 3D cultures did not achieve efficient HuNoV GI or GII viral replication (Takanashi et al., 2014), but Caco-2 cells growing in 3D cultures seemed to efficiently provide an appropriate environment to HuNoV replication (Straub et al., 2011).

Stem cell-derived human intestinal enteroids (HIEs) have served as efficient replication systems for various HuNoVs genotypes (Ettayebi et al., 2016), and has revealed the importance of bile fluids and HBGA in HuNoV infection (Murakami et al., 2020). Moreover, Hosmillo et al. (2020) recently demonstrated that the Janus activated kinase/signal transducer and activation of transcription (JAK/STAT) signaling-induced interferon pathway blocks HuNoV replication in intestinal enteroid cells (IEC) (Hosmillo et al., 2020). Inhibiting both the JAK/STAT pathway and the RNA polymerase II-dependent transcription increased HuNoV replication, resulting in a much more robust model for the study of HuNoV.

HuNoV infection and models

The study of HuNoVs has relied on volunteers (Atmar et al., 2008) and investigation of outbreaks (Fankhauser et al., 1998; Gallimore et al., 2004), and although this methodology is an efficient way to obtain high viral titers and study viral pathogeny, there are obvious ethical and practical reasons that make it problematic to say the least. Attempts to infect the most suitable animal models with HuNoVs through the oral or alternative pathways have been made with variable results (Cheetham et al., 2006; Souza et al., 2008; Wyatt et al., 1978). Recently, the infection of zebrafish *Danio rerio* embryo with HuNoV present in human stool samples represents a promising effective method to produce high viral titers (Van Dycke et al., 2019). Moreover, its tropism in the intestinal tract and hematopoietic lineage cells could signify that larvae can also serve to understand HuNoV pathogeny and pathology.

The immune response induced by caliciviruses

Innate immune response

The innate immune response to calicivirus infection is mainly mediated by the Interferon (IFN) pathway. MNV, HuNoV, and TV trigger this response through the Toll-like receptors (TLRs), melanoma differentiation-associated protein 5 (MDA-5), and the retinoic acid-inducible gene 1 (RIG-I) respectively (Dang et al., 2018; McCartney et al., 2008). During MNV infection, the innate immune response is potentiated by the IFN-induced protein with tetratricopeptide repeats 1 (Ifit1) (Mears et al., 2019), triggering

IFN-I pathway in all cases. Moreover, FCV 2280 strain initiates an IFN- β response and MNV, TV, FCV, HuNoV GII. 3, and NV are sensitive to IFN treatment (Dang et al., 2018; Enosi Tuipulotu et al., 2018; Fulton and Burge, 1985; Qu et al., 2016; Tian et al., 2015), suggesting that recombinant IFN could be used to treat diverse calicivirus infections. In this regard, IFN- ω , has been used to control FCV infections in Japan since 1994 (Minagawa et al., 1999; Yang et al., 2007).

Downstream the IFN pathway, IFN regulatory factor 1 (IRF-1) has been reported to hamper FCV and HuNoV replication in vitro (Dang et al., 2018; Liu et al., 2018).

Interestingly, the study of the IFN role in MNV replication can shed light on the viral mechanisms of spread and persistence in its host. In this regard, STAT-1 limits MNV infection to peripheral tissue in immunocompetent mice's intestine, preventing its dissemination to other organs (Mumphy et al., 2007). It is also known that infection with FCV (Foley et al., 2006), RHDV (Trzeciak-Rydzek et al., 2016) and with both noroviruses HuNoV or MNV induce the production of pro-inflammatory cytokines like Interleukin (IL)-8, tumor necrosis factor (TNF)- α , nitric oxide (NO₂) liberation, and/or IL-1 α . It is suggested that in acute HuNoV infection, a major Th1 and minor Th2 response is mainly established in infected humans (Newman et al., 2015) and gnotobiotic pigs (Souza et al., 2007), as the levels of the regulatory IL-10 cytokine also increase during infection.

As IFN can hamper calicivirus replication, caliciviruses have acquired mechanisms to impair this pathway at different steps. An interesting finding is that the FCV strains F9, Bolin, and HRB-SS, NV, and HuNoV GII.3 genotype do not trigger the IFN immune response (Qu et al., 2016; Tian et al., 2015). On the other hand, FCV F4 strain impairs the IFN response at transcriptional and post-translational levels, through the NS4 (p39) protein that, when transiently expressed, negatively modulates IFN- β and the ISG-15 transcription and prevents the activation of the IFN regulatory transcription factor 3 (IRF-3) by phosphorylation and dimerization, resulting in a deficient IFN-1 type response (Yumiketa et al., 2016).

Stress granules (SG) are ribonucleoprotein complexes that form in the cell cytoplasm as a response to diverse stimuli, including viral infections. These complexes contain stalled non-translated cellular mRNA attached to the translation complex, delaying cell translation rate to avoid viral protein production. Moreover, proteins involved in antiviral responses are recruited to SG, inducing their activation (reviewed in: Protter and Parker, 2016).

The FCV Urbana strain cleaves by the action of the viral protease, the GTPase-activating protein-binding protein (G3BP)-1 a key stress granule protein involved in antiviral response at multiple levels (Reineke and Lloyd, 2015). Similarly, the infection with MNV and HuNoV causes G3BP-1 (Humoud et al., 2016), relocation to the RC (Brocard et al., 2020), impairing SG nucleation while using it as a factor for Vpg-dependent translation (Brocard et al., 2020; Hosmillo et al., 2019).

In MNV infection, the G3BP1 targeting coupled with an impaired cytokine production through cell translational shutoff by eIF2 α phosphorylation (Fritzlar et al., 2019), results in an impaired cellular immune response without affecting viral protein production.

It is also known that PSaV impairs production of NO₂, a well-known antiviral agent, through Cyclooxygenase 2/Prostaglandin E₂ (COX-2) pathway activation likely due to Vpg and the protease/polymerase NS6/7 viral proteins (Alfajaro et al., 2017). Similarly, FCV an MNV activate the same pathway to reduce NO₂ production, although the mechanism is still unknown (Alfajaro et al., 2018).

MNV-induced lysis and pro-inflammatory cytokine release can be beneficial to viral persistence, as recruitment of macrophages and neutrophils to the infection site supplies the virus with an ongoing population of susceptible cells (Van Winkle et al., 2018).

Adaptive immunity

One of the main characteristics of the adaptive immune system is the ability to generate a specific immune memory against foreign agents and, thus to respond more efficiently to a second encounter with the same antigen. The adaptive response can be divided into a cellular and humoral immune response. While the humoral response is given by the antibodies produced by plasma cells, the cellular immune response is given by CD4⁺ and CD8⁺ T lymphocytes. However, viruses have evolved strategies that evade these specialized responses to complete their replication cycle, counteracting the host's immune system at different levels.

Cellular immune response

When a virus infects a cell, it is necessary to produce the cellular context required to generate the viral progeny that disseminate to neighboring cells. To control the expression of non-host proteins, major histocompatibility complex (MHC) class I, expressed in all nucleated cells, processes these proteins, and the resulting peptides are exposed to the outer face of the cell membrane. Cytotoxic CD8⁺ lymphocytes recognize these foreign peptides and destroy the infected cell. The cellular immune response to caliciviruses has not been studied in detail, and much remains to be learned about possible evasion mechanisms. Yet, the presence of specific CD4⁺ T lymphocytes against FCV in the spleen of cats vaccinated with FCV (de Groot-Mijnes et al., 2004). The presence of HuNoV GI.3 and GII.4 specific T lymphocytes in children under 4 years of age has been reported (Malm et al., 2019). Moreover, the stimulation with peptides of NoV GII.4-1999, GII.4-2012 (Sydney), and HuNoV GI.3 VP1 of peripheral blood mononuclear cells of patients with previous exposure to these HuNoV strains generates a good response of CD8⁺ T lymphocytes (Malm et al., 2016), suggesting the importance of the cellular immune response in the clearance of calicivirus infections.

To evade the cellular immune response, viruses have generated different strategies, such as decreasing the expression of MHC-I. During MNV infection, NS3 protein induces the degradation of MHC-I through the proteasome route and vesicular traffic control, impairing the antigenic presentation and activation of cytotoxic TCD8⁺ cells (Enosi Tuipulotu et al., 2017; Fritzlar et al., 2018). Another suggested mechanism for evading the immune response is the location of the infected cells in immune-privileged sites.

Infection with MNV induce robust CD8+ T cell responses, generating virus-specific CD8+ cells that maintain their ability to respond to their antigen, but paradoxically, viral replication is maintained. It is suggested that the virus remains in a place less accessible to these cytotoxic lymphocytes (Tomov et al., 2017), or that some strains generate lymphocytes with suboptimal responses (Tomov et al., 2013).

Humoral immunity

The study of humoral immunity in viral infections is of vital importance, especially for the development of vaccines. Due to the ability of many caliciviruses to re-infect the same host, the notion exists that calicivirus infection do not result in a robust immune response and factors necessary for the generation of efficient immune memory has been an important subject of study. Neutralizing antibodies are known to be key to the clearance of different caliciviruses (Chachu et al., 2008; Ferreira et al., 2008; Wensman et al., 2015), and each subtype of immunoglobulin will confer different efficiencies to eliminate the infection; with IgA having the greatest capacity for neutralization, elimination (Ramani et al., 2015) and cross-reaction against HuNoV (Lindesmith et al., 2015). Another suggested advantage is the great ability of neutralizing antibodies to block norovirus interaction with HBGAs (Sapparapu et al., 2016), although that the anti-HuNoV IgA-producing cells might have a shorter lifespan than IgG-producing cells (Lindesmith et al., 2015).

To avoid the antibody responses, caliciviruses have developed different strategies; one of them is the high mutational rates of the most immunogenic regions of their capsid proteins, which are the target for neutralizing antibodies, such as the P2 domain of VP1 (Iwakiri et al., 2009; Nilsson et al., 2003), which interacts directly with the viral cellular receptors. The virus must maintain a balance to evade the blockade of neutralizing antibodies without losing affinity for their cellular receptors; precisely, in the D epitope of the HuNoV strain GII.4 the amino acid change is generated in such a way that they can cause loss of antibody binding without ablation of the HBGA (Lindesmith et al., 2019). Other mechanisms that rely on small spatial rearrangements of the norovirus GI.1 and GI.4 capsid to reduce exposure time to neutralizing antibodies or steric hindrance by post-translational modifications were recently discussed in detail (Smith and Smith, 2019).

The infection of STAT1-deficient mice with the MNV-4 persistent and systemic strain causes the impairment of B cells development. A significant loss of pro-B/pre-B cells in the bone marrow of the immunodeficient but not in wild-type phenotype mice was observed. Even though the mechanism by which MNV-4 regulates the B cell maturation of STAT1-deficient mice is unknown, it may be related to decreased IL-7 levels, an important cytokine for B cell development, suggesting the role of B cells in the norovirus replication restriction (Hsu et al., 2018).

Concluding remarks

The *Caliciviridae* family includes infectious agents of medical, livestock, and veterinary interest, with HuNoVs nowadays being the leading cause of non-bacterial gastroenteritis outbreaks worldwide, responsible for 200,000 annual deaths in the developing countries. The continuous discovery of new caliciviruses in recent years has led up to the recent acceptance of six new viral genera, and their study might be beneficial to the better understand HuNoVs and the farming industry, as treatments or vaccines could be developed to prevent diseases and the subsequent economic loss.

New calicivirus models, as well as the recent development of effective HuNoV replication systems for the first time in nearly 50 years, are a major breakthrough that will lead to a rapid and better understanding of HuNoV molecular biology and pathogenesis. Yet, the advances made in the understanding of the calicivirus replication cycles in the last years need to be matched with advances in the understanding of the innate and adaptive viral immune responses to calicivirus, areas where much still need to be learned. This may provide the elements to sort out the difficulties in vaccine and treatment research that will help us to overcome the burden that caliciviruses have represented as human and animal pathogens.

Introduction

Bunyaviruses comprise a large group of RNA viruses that are worldwide pathogens and are mainly transmitted by arthropods, i.e., arthropod-borne viruses (arboviruses) or, in some cases, by aerosols from infected rodent excreta. The term 'Bunyavirus' is derived from the name of the location where the *Bunyamwera virus* was first isolated (Bunyamwera village, Uganda) during yellow fever surveillance in *Aedes* mosquitoes (Smithburn et al., 1946). Serological cross-reactions between this new virus with the *Wyeomyia* (Roca-Garcia, 1944), *Cache Valley* (Holden and Hess, 1959), and *Kairi* (Anderson et al., 1960) viruses led Casals and Whitman (Casals and Whitman, 1960) to sort them into a new antigenic group named "The Bunyamwera serogroup." Due to cross-reactivity between Bunyamwera and other related serogroups, such as Guama and Simbu, they were organized into the "Bunyamwera Supergroup" (Casals, 1963). Combining a total of 11 serogroups, including approximately 90 viruses, the new classification was: Bunyamwera, Bwamba, C serogroup, Capim, California, Guama, Koongol, Patois, Simbu, Tete, and Olifantsvlei. Strong antigen cross-reactions have been reported within each serogroup, as opposed to weak antigen cross-reactions among different serogroups (Murphy et al., 1973; Casals, 1971).

Ultrastructural analyses, at the electron microscope level, allowed researchers to determine that viruses belonging to the Bunyamwera serological supergroup were morphologically indistinguishable (Murphy et al., 1973). However, several other serogroups that are antigenically different, but morphologically similar to the Bunyamwera Supergroup, were also detected (Taylor, 1967). Therefore, the *Bunyaviridae* family name was proposed in order to organize these viruses (Murphy et al., 1973). In 1975, the Bunyamwera serological supergroup was recognized by the International Committee on Taxonomy of Viruses (ICTV) as the *Bunyavirus* genus, within the *Bunyaviridae* family (Fenner and Maurin, 1976). Likewise, unrelated viruses with morphological similarities but antigenic differences from the Bunyamwera serological supergroup were also sorted into the new *Bunyaviridae* family. Nevertheless, they were arranged in other genera (Murphy et al., 1973; Porterfield et al., 1975). Thus, viruses belonging to the *Bunyaviridae* family were characterized as: enveloped and spherical virions, with 90–100 nm in diameter; containing a single-stranded RNA genome, possibly arranged in several segments (generally three segments); membrane-spanning polypeptide spikes at the virus surface; and an internal ribonucleoprotein filament, measuring approximately 2–2.5 nm wide (Fenner and Maurin, 1976).

Several new serogroups were subsequently isolated and, despite presenting antigenic differences from the *Bunyavirus* genus, exhibited morphogenetic and molecular characteristics that were similar enough to warrant their addition to the *Bunyaviridae* family. These newly characterized serogroups were *Phlebovirus*, *Uukuvirus*, and *Nairovirus* (Bishop et al., 1980), which were later reorganized into genera and sorted into the *Bunyaviridae* family (Matthews, 1981). Thus, the *Bunyaviridae* family comprises four genera: *Nairovirus*, transmitted primarily by ticks carrying Crimean-Congo hemorrhagic fever virus (CCHFV) as its type species; *Phlebovirus*, transmitted by sandflies (Phlebotomus), with Sandfly fever virus (SFSV) as its type species; *Uukuvirus*, also transmitted by ticks, with Uukuniemi virus (UUKV) as its type species; and the *Bunyavirus* genus, transmitted mainly by mosquitoes, with Bunyamwera virus (BUNV) as its type species. The *Hantavirus* genus was later sorted into the *Bunyaviridae* family as its fifth genus due to molecular similarities (Schmaljohn and Dalrymple, 1983), and its type species was the Hantaan virus (HNTV), the etiological agent of hemorrhagic fever with renal syndrome (HFRS). Hantaviruses were peculiar in the *Bunyaviridae* family since their transmission is carried out by aerosol particles from small rodent secretions (Lennette et al., 1988). Due to molecular similarities, the *Phlebovirus* and *Uukuvirus* genera were considered related and were grouped into the *Phlebovirus* genus (Francki, 1991). Furthermore, on account of genomic similarities with the *Phlebovirus* genus, the recently established *Tospovirus* genus of plant-related viruses, with tomato spotted wilt virus (TSWV) as its type species, was also sorted into the *Bunyaviridae* family (Francki, 1991). Viruses from this family were generally called "bunyaviruses." Thus, in order to avoid further misstatement, in 2002, the *Bunyavirus* genus was renamed *Orthobunyavirus* (Mayo, 2002; Calisher, 2008). Therefore, the *Bunyaviridae* family was characterized as the largest RNA virus family, classified into five genera: *Orthobunyavirus*, *Hantavirus*, *Nairovirus*, *Phlebovirus*, and *Tospovirus* (Elliott, 2009).

*These authors contributed equally to this work and are cited alphabetically.

The development of bioinformatics and sequencing techniques enabled the establishment of better classification criteria based on comparative genomics and phylogenetic analyses. Metagenomic tools led to the discovery of new “bunya-like” species, containing two or more than three genome segments (Li et al., 2015; Tokarz et al., 2014; Elbeaino et al., 2009; van Poelwijk et al., 1997), which were reorganized into the *Bunyaviridae* family (Briese et al., 2016). Therefore, in 2016, the ICTV classified the *Bunyaviridae* family as the *Bunyavirales* order and rearranged the *Hantavirus*, *Nairovirus*, and *Tospovirus* genera into families (Briese et al., 2016). The committee also established the *Peribunyaviridae* family from the *Orthobunyavirus* genus and other genera, created the *Phenuiviridae* family, where the *Phlebovirus* and *Tenuivirus* genera were sorted, and the *Fimoviridae* family, where the *Emaravirus* genus was sorted. The *Feraviridae*, *Jonviridae*, and *Phasmaviridae* families were established for newly discovered invertebrate bunyaviruses (Briese et al., 2016). By 2016, the *Bunyavirales* order was divided into nine families (*Feraviridae*, *Fimoviridae*, *Hantaviridae*, *Jonviridae*, *Nairoviridae*, *Peribunyaviridae*, *Phasmaviridae*, *Phenuiviridae*, and *Tospoviridae*), and in 2017, the *Arenaviridae* family was included in this order due to phylogenetic relatedness (Guterres et al., 2017; Kuhn et al., 2017). Additionally, the *Feraviridae* and *Jonviridae* families were classified as genera and sorted into the *Phasmaviridae* family, and the *Cruliviridae*, *Myopoviridae*, and *Wupedeviridae* families were created to sort highly divergent and atypical newly discovered viruses (Kuhn et al., 2017). In 2019, the *Leishbuviridae* family was established to include the new genus *Shilevirus*, which infects trypanosomatid protists (Abudurexiti et al., 2019). Thus, the *Bunyavirales* order is currently divided into 12 families: *Arenaviridae*, *Cruliviridae*, *Fimoviridae*, *Hantaviridae*, *Leishbuviridae*, *Myopoviridae*, *Nairoviridae*, *Peribunyaviridae*, *Phasmaviridae*, *Phenuiviridae*, *Tospoviridae*, and *Wupedeviridae*.

Virus structure and organization

Bunyaviruses are enveloped viruses with spherical conformation that range between 80 and 120 nm in diameter (Ter Horst et al., 2019), with some hantaviruses presenting elongated morphology (Guardado-Calvo and Rey, 2017; Mittler et al., 2019). Arenaviruses are an exception, with pleomorphic virus particles ranging from 50 to 300 nm in diameter (Buchmeier, 2002; Murphy and Whitfield, 1975). Viral particles consist of four major structural proteins: the glycoproteins Gn and Gc; the nucleocapsid protein (N or NP); and the viral RNA-dependent RNA polymerase (RdRp) or L protein (Ter Horst et al., 2019). In addition, arenaviruses contain a zinc-binding matrix protein known as the Z protein (Salvato and Shimomaye, 1989). Also, the ssRNA genome is segmented and associated with the N and L proteins, forming ribonucleoprotein complexes (RNPs) (Olschewski et al., 2020). Structural proteins and virus genome morphology are described in Fig. 1.

N protein: The Bunyavirus N protein structure has been extensively investigated by atomic-resolution analyses (Guo et al., 2012; Olal and Daumke, 2016; Raymond et al., 2012; Reguera et al., 2013), which contributed to the current knowledge of the viral protein's structure and function. The N protein has a core domain where the RNA-binding cleft is located and extended arm or stalk domains, which enable protein oligomerization into several oligomer types, varying according to family and species (Sun et al., 2018). Each protomer's central RNA-binding cleft forms a continuous channel for single-stranded RNA coupling (Reguera et al., 2013). Several studies suggest diversity in N protein conformational changes during RNA binding or oligomerization that are responsible for the formation of RNPs (Sun et al., 2018; Carter et al., 2012; Wang et al., 2012).

L protein: The Bunyavirus L protein, or RdRp, is responsible for both viral genome transcription and replication (Gerlach et al., 2015). The structure of some bunyaviruses' RdRps has been solved by different groups (Gerlach et al., 2015; Peng et al., 2020), thus

Fig. 1 Bunyavirus particle morphology. (A) Tri-segmented bunyavirus particle structure. (B) Bi-segmented arenavirus particles. All Figures in this Chapter were drawn using BioRender.

contributing to the current knowledge of this viral protein's structure and function. Overall RdRp architecture consists of a large globular core domain and a flexible N-terminal region. The core domain presents polymerase activity and includes palm, thumb, finger, and fingertip domains (Sun et al., 2018). On the other hand, the N-terminal region harbors endonuclease activity (Gerlach et al., 2015) and is connected to the large globular core domain by a flexible linker (Sun et al., 2018).

Glycoproteins: Glycoproteins Gn and Gc (also termed GP1 and GP2 respectively, for Arenaviruses), which are encoded by the virus's M segment as a glycoprotein precursor, are type I integral membrane proteins (Ter Horst et al., 2019; Elliott, 2014) that arrange as heterodimer structures, spanning 5–10 nm projections at the viral surface (Guardado-Calvo and Rey, 2017). The size and structure of Gc and Gn vary considerably among bunyaviruses (Bowden et al., 2013; Elliott, 1996). Thus, the spike structures formed by these glycoproteins change substantially according to the virus family and genus, with hantaviruses possessing tetrameric square-like arrangements (Battisti et al., 2011), phleboviruses having pentamer or hexamer conformations (Huiskonen et al., 2009), and orthobunyaviruses presenting tripodal assembly (Bowden et al., 2013). Gc structural studies suggest that the glycoprotein has a class II fusion protein fold that is crucial for bunyavirus entry into host cells (Guardado-Calvo and Rey, 2017).

Arenavirus Z protein: This zinc-finger protein is the smallest structural protein of arenaviruses, containing 90–99 amino acids, and constitutes the virus matrix protein (Shao et al., 2018). This protein belongs to the RING-finger protein family (Salvato and Shimomaye, 1989) and has an important role in RdRp activity and virus budding regulation (Peng et al., 2020).

Non-structural proteins: Most bunyaviruses, depending on the species, may contain two non-structural proteins encoded by the virus's M and S segments, NSm and NSs, respectively (Ter Horst et al., 2019). Although these proteins are not essential for virus replication, they may be involved in viral assembly, apoptosis, protein synthesis inhibition, and immune evasion (Elliott, 2014; Shi et al., 2006; Soldan and González-Scarano, 2014). In addition, other non-structural proteins, such as VP3 in some phasmaviruses (Li et al., 2015) and p4, p5, and p6 in some fimoviruses (Sun et al., 2018), are less frequently found and do not have a known function.

Genome: The segmented single-stranded RNA genome has a negative-sense polarity, and, according to the family, some viruses may also use an ambisense coding strategy (Olschewski et al., 2020). Each segment has complementary regions at its 5'- and 3'- ends (Elliott, 1996) that are highly conserved within each genus, allowing for a panhandle structure conformation, which contains genome replication and transcription promoters (Wichgers Schreur et al., 2018). The number of genome segments may vary between two and eight, according to virus family and species (Li et al., 2015; Moolla and Weyer, 2020). However, the vast majority of Bunyaviruses possess a tri-segmented genome (Li et al., 2015; Ter Horst et al., 2019). Their genomic structure and coding strategies are detailed in Fig. 2.

Bunyavirus replicative cycle

The life cycle of these viruses has been studied primarily in mammalian cells (Albornoz et al., 2016), and several receptors were identified to be involved in bunyavirus cell entry, with the most well-described being: DC-SIGN, L-SIGN, NMMHC-IIA (non-muscle myosin heavy chain IIA), Heparan sulfate, β 1- β 3 integrins, protocadherin-1, α -DC (alpha-dystroglycan), and hTfR1 (human transferrin receptor 1) (Albornoz et al., 2016; Jangra et al., 2018; Léger et al., 2016; Radoshitzky et al., 2007; Reignier et al., 2006; Riblett et al., 2016; Suda et al., 2016).

Cellular receptors interact with viral proteins to mediate virus entry by endocytosis, in which, for most bunyaviruses, the endocytic pathway involves clathrin-coated vesicles (Garrison et al., 2013; Hollidge et al., 2012; Jin et al., 2002; Santos et al., 2008; Shtanko et al., 2014). However, other bunyaviruses' cell entry may also involve caveolin-dependent mechanisms or micropinocytosis (de Boer et al., 2012; Harmon et al., 2012). Therefore, the diversity of bunyavirus endocytosis pathways highlights their ability to use alternative endocytic routes (Albornoz et al., 2016). When in endocytic vesicles, viral membrane fusion takes place either in early endosomes, late endosomes, or lysosomes, depending on the virus species, in light of the required pH for such event (Albornoz et al., 2016). Membrane fusion is mediated by viral Gc, which exposes hydrophobic domains when in the presence of high endosomal K^+ concentrations and low pH, allowing for virus-cell membrane interactions and fusion, thus releasing RNPs into the cell cytosol (Charlton et al., 2019; Hover et al., 2018), where this complex will be disassembled to enable N and L gene transcription. Seeing that these proteins are crucial for the first steps of virus replication, they are prioritized in virus genome transcription (Fig. 3) (Ferron et al., 2017).

Viral transcription initiation is carried out through a Cap-Snatching mechanism by the L protein endonuclease domain (Olschewski et al., 2020), followed by transcription elongation, which is coupled with viral protein translation (Barr, 2007). The next step, known as transcription termination, is characterized by a specific conserved termination signal sequence that can promote hairpin structure formation (Sun et al., 2018; Ferron et al., 2017). It has been proposed that cytosolic N protein accumulation triggers genome replication by the RdRp polymerase domain (Elliott, 2014; Ferron et al., 2017) in two consecutive steps: complementary RNA (cRNA) is synthesized "de novo" in a primer-independent manner from viral RNA (vRNA), followed by cRNA synthesis into new generation vRNA (Fig. 3) (Sun et al., 2018; Peng et al., 2020; Ferron et al., 2017). Newly synthesized cRNA and vRNA are hijacked by the viral N protein, constituting cRNPs and vRNPs, respectively (Sun et al., 2018). In the cell cytosol, vRNPs derived from the viral M segment are transcribed into mRNA, followed by glycoprotein precursor (GP) translation initiation (Ferron et al., 2017). A signal sequence in the GP targets the Endoplasmic reticulum (ER) for further translation and glycoprotein processing (Cifuentes-Muñoz et al., 2014; Gerrard and Nichol, 2007). ER proteases are thought to cleave GPs into glycoproteins

Fig. 2 Bunyavirus coding strategies. (A) Tri-segmented genome coding strategies of negative-sense viruses. (B) Bi-segmented genome coding strategies of ambisense viruses.

Gn and Gc, which will be further processed (Guardado-Calvo and Rey, 2017) and targeted to other organelles after glycoprotein dimerization (Cifuentes-Muñoz et al., 2014; Lappin et al., 1994). Most bunyaviruses are targeted to the Golgi complex for virus assembly and budding, whereas arenaviruses and some hantaviruses are targeted to the plasma membrane for such events (Fig. 3) (Guardado-Calvo and Rey, 2017; Elliott, 2014; Cifuentes-Muñoz et al., 2014; Burri et al., 2012).

At the targeted organelle, glycoprotein heterodimers associate into large complexes, interacting laterally, to induce membrane curvature deformation for viral protein budding (Guardado-Calvo and Rey, 2017). The recruitment of components of the cellular endosomal sorting complex required for transport (ESCRT) machinery has been reported to support such membrane curvature (Cifuentes-Muñoz et al., 2014; Burri et al., 2012; Barbosa et al., 2018). Arenaviruses, for instance, promote membrane deformation by Z protein oligomerization (Burri et al., 2012). It has been suggested that vRNP packaging into viral particles is mediated by glycoprotein cytosolic tail interactions with the N protein (Wichgers Schreur et al., 2018). In arenaviruses, this process is orchestrated by the Z protein (Burri et al., 2012). Although there is some selectivity in vRNP packaging, which appears to be driven by the 5'- and 3'- untranslated regions, evidence showing that vRNP packaging into viral particles is a stochastic process has also been reported (Wichgers Schreur et al., 2018). After virus assembly in Golgi compartments, as occurs in most bunyaviruses, viral particles are targeted to the plasma membrane and are transported through cytoskeleton filaments (Elliott, 2014; Cifuentes-Muñoz et al., 2014; Sanz-Sánchez and Risco, 2013; Shi et al., 2010). The main steps of the bunyavirus replicative cycle are described in Fig. 3.

Fig. 3 Bunyavirus replicative cycle. (1) Bunyaviruses bind to specific cellular receptor. (2) Most viral particles enter host cell via endocytic vesicles; (3) Viral particles are trafficked through early endosomes to late endosomes; (4) Membrane fusion takes place either in early endosomes, late endosomes, or lysosomes, depending on virus species, for vRNP release into the cell cytosol; (5) Transcription of the N and L genes are prioritized for further virus replication; (6) N and L protein translation; (7) First step of virus replication into cRNPs; (8) Second step of virus replication into vRNPs; (9–10) Transcription of the M and Z genes, respectively; (11–12) Glycoprotein precursor and Z protein translation, respectively; (13) Glycoprotein precursor processing in the Endoplasmic reticulum; (14) Glycoproteins trafficking within the secretory pathway; (15–16) Virus budding into the Golgi complex and at the plasma membrane, respectively. Even though hantaviruses may also bud in the plasma membrane, they do so without Z protein activity.

Bunyavirus immune evasion

Viral genome released into the cytosol may be detected by the retinoic acid-inducible gene I (RIG-I)-like receptors (RLRs) family of RNA sensors, such as RIG-I and melanoma differentiation-associated gene 5 (MDA5), leading to the activation of antiviral host responses. Upon viral RNA binding, RLRs activate the mitochondrial antiviral signaling (MAVS) protein, a signaling transduction adaptor. This activates interferon regulatory factors (IRFs) that, together with the nuclear factor κ - β (NF- κ β) transcription factor, induce the expression of type-I interferon (IFN) and other genes to counteract virus infection (Rehwinkel and Gack, 2020). Interferon response is accomplished in two stages, termed initiation and amplification. The initiation stage is when IFN- α/β expression is activated, leading to its secretion. Meanwhile, the amplification stage is when secreted IFN- α/β binds to IFN receptors (IFNARs) at the cell surface, activating the JAK/STAT signaling pathway, resulting in the expression of interferon-stimulated genes (ISGs), thus inducing an antiviral state that provides a crucial defense against viral infection (Eifan et al., 2013; Le May and Bouloy, 2012). Most bunyaviruses are able to evade these cellular immune responses due to NSs activity by shutting down IFN gene expression. Alternatively, some bunyaviruses escape immune recognition by the activity of other viral proteins, as described below (Fig. 4).

Viruses from the *Peribunyaviridae* family were shown to prevent IFN responses via NSs, with this viral protein inhibiting RNA polymerase II (RNA Pol II) activity and thereby blocking host cell mRNA elongation. For instance, BUNV blocks the phosphorylation of the C-terminal domain of RNA Pol II, inhibiting host cell transcription (Léonard et al., 2006). Moreover, infection with this virus specifically prevents IFN- β expression by restraining NF- κ β and IRF-3 activation (Weber et al., 2002). Similarly, LACV inhibits type-I IFN response (Thomas et al., 2004) by inducing the proteasomal degradation of RNA pol II subunit RBP1 (Verbruggen et al., 2011), which shuts down the whole cell's transcription, including IFN and IFN-related genes. Furthermore, Schmallenberg virus (SBV) NSs has an important role in inhibiting IFN expression (Varela et al., 2013), although this mechanism has not yet been fully described. On the other hand, it was shown that OROV NSs is essential to antagonize IFN response, where OROV NSs infection

Fig. 4 Bunyavirus cellular immune evasion. Upon viral genome release into the cell cytosol, the exposed foreign genome can be detected by nucleic acid sensors such as RIG-I and MDA5, which will trigger cellular antiviral responses. Bunyaviruses have evolved to inhibit various cellular immune recognition pathways that lead to IFN or IFN related genes expression. (1) The Lymphocytic Choriomeningitis Virus (LCMV) Z protein and (2) the New York-1 hantavirus (NY-1V) GnCT protein inhibit the RIG-I recognition pathway. (3) The Severe Fever with Thrombocytopenia Syndrome Virus (SFTSV) NSs protein relocates RIG-I to viral inclusion bodies. (4) The Crimean-Congo Hemorrhagic Fever Virus (CCHFV) L protein can block RIG-I mediated IFN response through its vOTU domain that removes Ub conjugates from RIG-I, inactivating it. (5) Rift Valley Fever Virus (RVFV) NSs protein can induce proteasome degradation of antiviral PKR protein. (6) The Andes Virus (ANDV) NSs protein inhibits MAVS signaling. (7) The Rift Valley Fever Virus (RVFV) NSs protein inhibits the assembly of transcription factor II, suppressing host cell transcription. (8) Bunyamwera Virus (BUNV) NSs protein inhibits RNA pol II activity through blocking its C-terminal domain phosphorylation, whereas (9) the La Crosse Virus (LACV) NSs protein inhibits RNA pol II activity by inducing the degradation of RNA pol II BDP1 subunit via the proteasome. Finally, (10) SFTSV NSs protein relocates STAT proteins to viral inclusion bodies, thus inhibiting STAT phosphorylation and signaling.

increased IFN production and induced STAT1 phosphorylation and ISG MxA expression (Tilston-Lunel et al., 2015). Thus, viruses from the *Peribunyaviridae* family are very effective in counteracting host cell immune evasion, with the NSs protein playing a significant role in this process. Nevertheless, the effectiveness of viral antagonism to IFN response may vary according to the infection environment. For instance, knock-out (KO) mice for IFNAR, MAVS, IRF-3, and IRF-7, when infected with OROV, presented an increased lethality when compared to wild-type animals (Proenca-Modena et al., 2015). In human peripheral blood cells treated with anti-IFNAR antibodies, which prevent IFN from binding to its receptor, OROV infection was significantly increased compared to non-treated samples (Ribeiro Amorim et al., 2020), indicating that activation of the IFN response was essential to restrict OROV replication in human PBMCs.

Rift Valley Fever virus (RVFV), from the *Phenuiviridae* family, has the ability to evade cell immune recognition in at least three different ways. At early hours (3–6 h) post-infection, RVFV blocks IFN- β gene expression through the action of its NSs protein (Le May et al., 2008), which translocates to the nucleus of infected cells and forms filamentous structures that bind several nuclear proteins, including subunits of an IFN- β gene corepressor complex. As a result, NSs stabilizes the association of the corepressor complex with the IFN- β gene promoter, thus inhibiting recruitment of the transcription factor YY1 and the transcriptional co-activator CBP. Altogether, IFN- β expression is blocked, allowing virus replication to progress in infected cells (Le May et al., 2008).

At later hours post-infection, RVFV suppresses host cell transcription by inhibiting the assembly of transcription factor II (TFIIH), which plays a role in the transcription of several protein-coding genes (Le May et al., 2004). NSs nuclear filaments recruit TFIIH

subunits, inhibiting TFIIF assembly and leading to proteasome degradation of p62, an essential subunit for TFIIF function (Kalveram et al., 2011). In addition to shutting down IFN- α/β and further cellular gene transcription, RVFV is also capable of degrading the antiviral factor double-stranded RNA-dependent protein kinase (PKR). This antiviral factor, which inhibits virus replication by blocking both viral and cellular mRNA translation (García et al., 2007), was shown to be essential for IFN- α/β production in virus-infected cells and the regulation of IFN- α/β mRNA stability (Schulz et al., 2010). RVFV NSs directs PKR to proteasome degradation, thereby displaying an additional anti-IFN property compared to other bunyaviruses (Habjan et al., 2009).

Moreover, another phlebovirus called Severe Fever with Thrombocytopenia Syndrome virus (SFTSV) also suppresses IFN-I and IFN-III signaling via NSs activity. Specifically, this protein can associate with and/or recruit RIG-I, STAT1, and STAT2 to viral inclusion bodies, suppressing IFN and ISG expression by inhibiting RIG-I activation, STAT phosphorylation, and nuclear translocation (Chaudhary et al., 2015; Santiago et al., 2014; Ning et al., 2015). Additionally, it was also shown that SFTSV NSs stabilizes and activates TPL2 (tumor progression locus 2) to induce IL-10 expression, an anti-inflammatory cytokine that limits host immune responses, enabling the progression of viral infection (Choi et al., 2019). Therefore, phleboviruses have efficient strategies for counteracting the host immune response to evade the IFN system to achieve viral replication.

Most viruses from the *Hantaviridae* family do not possess an NSs ORF in their S segment. Thus, some pathogenic hantaviruses evade cellular immune response by inhibiting IFN activation by the action of their glycoproteins and nucleoprotein. The New York-1 hantavirus (NY-1V) Gn cytosolic tail is capable of inhibiting the RIG-I pathway, blocking the transcription of type I IFN genes and, consequently, suppressing the IFN pathway (Alff et al., 2006). On the other hand, hantaviruses that encode an NSs protein, such as the Andes virus (ANDV), can inhibit the IFN pathway by NSs RIG-I and MDA5 downstream signals recognition suppression (Vera-Otarola et al., 2020). The Hantaan virus (HNTV) is able to counteract cell antiviral activation by a different pathway, where the nucleoprotein inhibits the tumor necrosis factor- α (TNF- α) of the NF- κ B pathway to prevent host immune detection (Taylor et al., 2009). Thus, hantaviruses possess different viral factors involved in host cell immune evasion, which appear to be distinct from most of the other bunyaviruses.

Viruses from the *Nairoviridae* family, which also do not present an NSs ORF, use a very peculiar immune evasion mechanism among bunyaviruses involving the cellular ubiquitin-proteasome system. Ubiquitin (Ub) conjugation to proteins plays an important regulatory role in host cell detection and response to virus infection. Upon IFN signaling pathway activation, various cellular proteins are posttranslationally modified by ubiquitination or SGylation, i.e., the conjugation of interferon-stimulated gene 15 (ISG-15) protein, an Ub-like protein. Some viruses have developed an escape mechanism that removes Ub and/or Ub-like moieties from host cell proteins, resulting in IFN pathway suppression (Isaacson and Ploegh, 2009).

In fact, cells express deubiquitinating (DUB) enzymes with an ovarian tumor-like (OTU) domain, which are involved in IFN response suppression by hydrolyzing Ub from cellular proteins (Nijman et al., 2005; Kayagaki et al., 2007). Interestingly, Nairoviruses' L protein contains a viral OTU domain homolog (vOTU) at the N terminus involved in IFN response suppression and immune response evasion. This domain was found to remove Ub and/or ISG-15 from specific substrates. Specifically, CCHFV vOTU deubiquitinase and deISGylase activity were, respectively, shown to be critical for virus-mediated suppression of IFN expression and to inhibit interferon-induced protein ISGylation, allowing CCHFV to evade immune responses (Scholte et al., 2017). Interestingly, there is a diversity among Nairoviruses' vOTU domain activity towards ISG-15 and Ub-conjugated proteins, which is related to the vOTU's primary structure (Capodagli et al., 2013).

Arenaviruses also lack an NSs ORF, as do nairoviruses. Pathogenic Arenaviruses' Z and N proteins are capable of inhibiting IFN response. In order to determine the involvement of arenavirus N protein in IFN inhibition, the Lassa virus (LASV) N protein structure was solved, and when specific mutations at the exonuclease activity domain of this viral protein were inserted, IFN expression was disrupted. Since the arenaviruses' N protein is highly conserved, the study was only performed with LASV (Qi et al., 2010). Arenaviruses' Z protein is able to inhibit RIG-I and MDA5 recognition and disrupt MAVS activation, leading to IFN expression blockage. Cellular immune evasion by Z protein activity was conserved among several pathogenic arenaviruses (Xing et al., 2015).

Therefore, bunyaviruses hold a variety of viral factors capable of evading host cell defenses, thus characterizing them as difficult pathogens to counteract in an infected cell.

Pathogenesis and the need for vaccines

Bunyaviruses are the etiological agents of several human and non-human diseases. Considered emergent viruses, the need for specific and efficient vaccines is crucial to avoid virus spread, followed by severe outbreaks, which may lead to human and/or animal deaths.

The pathogenesis of orthobunyaviruses differs according to virus species. For instance, OROV and LACV, found in South and North America, respectively, may cause febrile illness in humans that, in rare cases, can lead to meningoencephalitis or meningitis (Sakkas et al., 2018; Taylor and Peterson, 2014). On the other hand, Schmallenberg virus (SBV), which is incident in Europe, is a teratogenic virus infecting domestic or wild ruminants (Hoffmann et al., 2012; Wernike and Beer, 2020). BUNV, the prototype of the orthobunyavirus genus, mainly found in the Americas and African countries, causes dengue-like disease, with fever symptoms in humans or neurological deterioration in animals, which may lead to death (Tauro et al., 2012, 2015).

Vaccine strategies to counteract orthobunyavirus infection have not been completely established, although some studies have made substantial efforts to achieve virus neutralization. The SBV Gc N-terminus vaccine, in a regular mammalian vector system, provided some immunization in cattle (Wernike et al., 2017), but when the same SBV domain was constructed in a modified Vaccinia virus Ankara vector, it granted full protection against SBV in those animals (Wernike et al., 2018). Further studies solved this N-terminus Gc structure and showed that it corresponds to glycoprotein head and stalk domains (Hellert et al., 2019). IFNAR KO mice models immunized with SBV Gc head and stalk domains presented sterile immunity when challenged with SBV, and the viral genome load was not detectable in those animals (Hellert et al., 2019). These studies show that the SBV Gc head and stalk domains' peptide and, potentially, equivalent domains of other Bunyaviruses, are strong candidates for future vaccine strategies. Furthermore, LACV studies were conducted in immunized IFNAR KO mice with the DNA-encoding viral glycoproteins Gn and Gc as a vaccine strategy. After the LACV challenge, there was a strong production of neutralizing antibodies against viral glycoproteins. In contrast, when IFNAR KO mice were immunized with the LACV N protein, no neutralizing antibodies were detected (Schuh et al., 1999). Studies on OROV vaccine strategies are unavailable in the literature, although bioinformatics assessments have attempted to predict the immunogenic viral protein and its possible cellular targets. Highly conserved predicted T-cell and B-cell epitopes were found to be promising interaction sites for the OROV M polyprotein, a fact that may indicate specific sites for future vaccine design (Adhikari et al., 2018).

Pathogenic viruses from the *Phenuiviridae* family, such as SFTSV and RVFV, cause significant liver damage in infected patients with increased serum liver enzymes. Mild cases of SFTSV and RVFV present febrile illness; however, in severe cases, SFTSV can lead to thrombocytopenia and multiorgan dysfunction (Yu et al., 2011), while RVFV can cause significant neurological damage (Alrajhi et al., 2004). Efforts for the development of vaccines to counteract either RVFV or SFTSV have been made, but without any strong leading candidates. SFTSV was only recently discovered, and vaccine studies against this virus have been quite challenging due to the lack of animal models that replicate human symptoms (Reece et al., 2018). Fortunately, ferrets proved to be very useful for SFTSV studies since they recapitulate human clinical symptoms (Park et al., 2019) and have been used as research tools to investigate SFTSV vaccines using different DNA vaccine strategies. Gc and Gn vaccines showed higher levels of neutralizing antibodies, with significant immune protection against SFTSV. In contrast, the same phenotype was not observed with the vaccine containing the N, NSs, and RdRp genes (Kwak et al., 2019).

Currently, there are at least two ongoing vaccine investigations for humans against RVFV: formalin-inactivated (TSI-GSD-200) and live-attenuated (MP-12) vaccines. Although TSI-GSD-200 presents mild side effects at tolerable levels, it demands multiple doses in humans to achieve viral protection (Rusnak et al., 2011). MP-12, on the other hand, requires a single dose to provide neutralizing activity and is currently under phase-II clinical trials (Pittman et al., 2016). However, abortion and teratogenic side effects were observed in animals vaccinated during early pregnancy with MP-12 (Hunter et al., 2002). Thus, MP-12 raises a concern for pregnant women who need vaccines against RVFV. An adenovirus-based vector expressing RVFV Gn and Gc was tested in early pregnant animals, which presented high neutralizing antibody titers after a single inoculation dose, without any teratogenic side effects. This vaccine is currently being developed for human testing (Stedman et al., 2019).

Hantaviruses are divided into old world (OW) hantaviruses, mainly located in Europe and Asia, and new world (NW) hantaviruses, found in the Americas. OW hantaviruses are the etiological agents of hemorrhagic fever with renal syndrome (HFRS), with a 1–2% mortality rate, and include HTNV, Seoul virus (SEOV), Puumala virus (PUUV), and Dobrava virus (DOBV). NW hantaviruses are the etiological agents of hantavirus cardiopulmonary syndrome (HCPS), with a 40% mortality rate, and include ANDV and Sin Nombre virus (SNV) (Kruger et al., 2015). The pathogenesis of these viruses involves mainly the endovascular system, where they suppress $\alpha\text{v}\beta 3$ integrin, leading to vascular permeability, plasma leakage, and may even induce hemorrhage (Gavrilovskaya et al., 1999, 1998). Several vaccine strategies have been developed to counteract pathogenic hantaviruses, and the most promising ones are DNA vaccines designed for Gn and Gc glycoprotein expression (Engdahl and Crowe, 2020). The hantavirus DNA vaccine designed using HNTV and PUUV M segment cDNA presented high levels of neutralizing antibodies in hamsters and non-human primates, with promising results for future vaccines (Hooper et al., 2001). Indeed, those vaccines progressed to clinical trials and, to date, are in phase-I trial. HNTV and PUUV vaccines were delivered to individuals by intramuscular electroporation and exhibited significant seroconversion in vaccinated participants (Hooper et al., 2014). Another group showed that the HNTV vaccine constructed with Gc or Gn cDNA fused with the lysosomal-associated membrane protein (LAMP) cytosolic tail resulting in high titers of neutralizing antibodies and long-term immunity in mice (Jiang et al., 2018, 2017). On the other hand, vaccine strategies with inactivated HNTV have also been used, but with little success when compared to DNA-based ones (Yi et al., 2018; Jung et al., 2018). Therefore, among the several hantavirus vaccine strategies that are being developed, so far, DNA vaccines are the most promising ones.

The most studied and well-establishedairovirus is CCHFV due to its 30% mortality rate. Located mainly in Europe, Asia, and Africa, CCHFV infection leads to disseminated intravascular coagulation in patients (Swanepoel et al., 1989); it is still unclear if the virus causes vascular permeability, as previously suggested (Bente et al., 2013). Studies in mild or severely infected patients indicated high serum levels of the inflammatory markers: TNF- α , IL-6, IFN- γ , and IL-10 (Saksida et al., 2010; Ergonul et al., 2006). Necropsy histopathological analyses of CCHFV infected patients revealed massive liver damage, with eosinophilic necrotic hepatocytes and hypertrophic Kupffer cells positive for virus antigen (Bente et al., 2013). Similarly to hantaviruses, CCHFV vaccine strategies were based on DNA and inactivated vaccines. However, mouse models for CCHFV vaccine studies have not rendered promising results due to the lack of vaccine immunogenicity (Spik et al., 2006). Therefore, new studies have been carried out in IFNAR KO mice for such research since they are considered immunocompromised animals. Indeed, when treated with the M segment cDNA-based vaccine, followed by CCHFV infection, 60% of the immunocompromised animals exhibited virus

protection (Garrison et al., 2017). In contrast, the Adenovirus-based vaccine expressing CCHFV-N in IFNAR KO mice, followed by virus infection, presented partial protection against CCHFV, and no viral protein was detected in liver tissue (Zivcec et al., 2018). A plasmid DNA-based vaccine encoding for Ub-linked versions of CCHFV Gn, Gc, and the nucleoprotein (N) has also been developed, as well as another vaccine strategy based on transcriptionally competent virus-like particles (tc-VLPs). The DNA virus-based vaccine provided 100% viral protection in IFNAR KO mice, with Th1 immune response and high levels of neutralizing antibodies. Although tc-VLPs-treated mice also presented high neutralizing antibody levels, a relatively low survival rate (40%) was observed after CCHFV infection. Therefore, the CCHFV DNA virus-based vaccine encoding for viral Ub-linked versions of Gn, Gc, and N showed to be an excellent candidate for further studies on CCHFV vaccine design (Hinkula et al., 2017). Although the CCHFV-inactivated vaccine is the only one currently approved, its use is exclusively for Bulgarian soldiers in endemic areas. Vaccinated individuals were reported to exhibit robust T-cell activity, as measured by serum IFN- γ , albeit with low levels of neutralizing antibodies (Mousavi-Jazi et al., 2012). Therefore, seeing that there are no strong leading vaccine candidates for CCHFV, further studies are required in order to establish a safe vaccine.

Arenaviruses are highly pathogenic viruses that, similarly to hantaviruses, are divided into new world (NW) arenaviruses, located in the Americas, and old world (OW) arenaviruses, found in West African countries. Pathogenic arenaviruses may cause hemorrhagic fever, with symptoms that can vary between NW and OW arenaviruses (vascular damage and liver damage, respectively) (Brisse and Ly, 2019). LASV, for example, is an OW arenavirus that has a 20% mortality rate. Although several LASV vaccine trials have been conducted, no leading candidate has been approved up to date. The LASV VLPs vaccine strategy, which expresses the viral glycoprotein precursor, has been shown to trigger mice T-cell response. However, it did not induce neutralizing antibody production against viral glycoproteins (Wang et al., 2018). A recombinant vaccinia virus vaccine expressing LASV glycoproteins in non-human primates (NHP) prevented animal death after virus challenging (Fisher-Hoch et al., 1989, 2000). Nonetheless, when expressing the LASV N protein, the mortality rate reached up to 80% (Fisher-Hoch et al., 2000). Moreover, inactivated LASV did not induce humoral protection in vaccinated challenged NHP, a fact that led to high levels of animal death after infection (McCormick et al., 1992). Interestingly, a DNA vaccine expressing LASV glycoproteins, introduced by dermal electroporation, provided full protection in NHP without any signs of Lassa fever symptoms (Cashman et al., 2017). Therefore, the DNA vaccine expressing LASV glycoproteins seems to be the most promising vaccine strategy to counteract LASV infection and is currently under further study regarding vaccine safety. Junin virus (JUNV) is a NW arenavirus and is the etiological agent of Argentinian hemorrhagic fever. A leading vaccine candidate is the JUNV strain Candid #1, a virus-attenuated strategy (Grant et al., 2012) that is already in use in endemic regions. This vaccine presents high protection efficacy (Maiztegui et al., 1998) but has not been approved by the Food and Drug Administration. Therefore, it is only used in Argentinian hemorrhagic fever endemic regions.

Several attempts have been made to design vaccines against bunyaviruses. Currently, there are important data showing possible leading vaccine candidates, or viral protein targets, for different bunyaviruses. Meanwhile, antibody-based therapies could represent a viable option in the battle against life-threatening bunyavirus infections. In this regard, a recent study using engineered multimeric single-domain antibody complexes against RVFV and SBV revealed that these molecules were highly effective in reducing and preventing morbidity and mortality in mouse infection models (Wichgers Schreur et al., 2020). Hopefully, in the near future, vaccines and antibody therapies will be developed to avert bunyavirus spread.

Introduction

Rabies virus (RABV) causes an acute neurological disease (called rabies) in humans and animals that is almost 100% fatal once infected hosts are symptomatic (reviewed in [Fooks et al., 2014, 2017](#); [Davis et al., 2015](#); [Fisher et al., 2018](#); [Du Pont et al., 2019](#)). Rabies is considered to be as the deadliest neglected tropical disease. RABV invades the central nervous system (CNS) in humans and provokes various symptoms including hydrophobia (fear of water), aggressiveness, agitation, confusion, hallucinations, muscle spasms, convulsions, and/or paralysis within 1–2 weeks prior to death. Rabies is one of the oldest infectious diseases in human history. The Laws of Eshnunna (c.1930 BCE) in ancient Mesopotamia evidenced that this zoonotic deadly disease transmitted from rabid dogs to humans was already recognized 4000 years ago ([Tarantola 2017](#)). Louis Pasteur and Emile Roux demonstrated for the first time in the 1880s that rabies is a vaccine preventable disease in dogs and humans and their achievement thus opened a new era in vaccine development. Although highly effective and safe vaccines and neutralizing antibodies against RABV are currently available (reviewed in [Tantawichien and Rupprecht, 2020](#)), RABV still kills nearly 60,000 people worldwide every year. In most cases, people acquired rabies from dog bites in developing countries with lower vaccination coverage in domestic dogs. In humans, clinical signs and symptoms of rabies are observed after variable asymptomatic periods (1 week to >1 year, average 2–3 months), which may be determined by various factors including initial infection sites, viral loads, viral pathogenicity, and host immunity. RABV is also known to be transmitted to humans from wild animals, such as bats, raccoons, skunks, foxes, mongooses, coyotes, and jackals, although in rare cases. Furthermore, RABV-like lyssaviruses, such as Australian bat lyssavirus, European bat lyssaviruses 1 and 2, Irkut virus, Duvenhage virus, and Mokola virus were reported to cause rabies-like diseases in humans (reviewed in [Johnson et al., 2010](#); [Fisher et al., 2018](#); [Fooks et al., 2017](#)). Therefore, the diseases caused by lyssaviruses remain significant public health threats.

RABV is a member of the *Lyssavirus* genus of the *Rhabdoviridae* family within the order *Mononegavirales* (reviewed in [Lyles et al., 2013](#)). Viruses belonging to the order *Mononegavirales* possess a negative-sense monopartite RNA genome (rarely bipartite genomes) and are called non-segmented negative strand (NNS) RNA viruses or mononegaviruses (reviewed in [Lamb 2013](#)). NNS RNA viruses are highly diversified eukaryotic viruses infecting vertebrates, invertebrates, plants, and/or fungi, and include important human pathogens, such as measles (*Paramyxoviridae*), Nipah (*Paramyxoviridae*), human respiratory syncytial (*Pneumoviridae*), and Ebola (*Filoviridae*) ([Lamb 2013](#); [Maes et al., 2019](#)). The family *Rhabdoviridae* consists of 30 genera that include 191 species as of 2020. Historically, vesicular stomatitis virus (VSV, an arthropod-borne animal rhabdovirus) belonging to the *Vesiculovirus* genus has served as an excellent model to study basic biology of rhabdoviruses and, by extension, other NNS RNA viruses. RABV and VSV share many common mechanisms involved in various aspects of viral replication in host cells, although RABV manifests its pathogenic properties quite differently from VSV. The major breakthrough in NNS RNA viral research was the development of a reverse genetics system for RABV that allows generation of recombinant viruses from cDNAs ([Schnell et al., 1994](#)). Studies using the reverse genetics system have led to deeper understanding of RABV gene functions in viral replication as well as pathogenesis. Furthermore, recent structural, biochemical, and cell biological studies have provided new insights into the roles of individual RABV proteins in each step of the viral life cycle. This chapter describes our current knowledge on various aspects of RABV infection.

Genome and virion structures

The RABV genome with approximately 11,900 nucleotides (nt) in length consists of five genes encoding the nucleocapsid (N), phospho- (P), matrix (M), glyco- (G), and large (L) proteins in the order 3'-N-P-M-G-L-5' similarly to other rhabdoviral genomes, such as the VSV genome ([Fig. 1A](#)) ([Tordo et al., 1986a, b, 1988](#); [Conzelmann et al., 1990](#)). The genome is encapsidated with the N proteins (450 amino acids) ([Iseni et al., 1998](#); [Schoehn et al., 2001](#)) to form a helical nucleocapsid, which serves as a template for

Fig. 1 Schematic diagrams of the RABV genome and particle. (A) The genomic structure of RABV (upper) is compared with that of VSV (lower). The positions of the nucleocapsid (N), phospho- (P), matrix (M), glyco- (G), and large (L) genes in their genomes are shown with a scale bar (knt, kilo nucleotides). The L gene products possess RNA-dependent RNA polymerase (RdRp), GDP polyribonucleotidyltransferase (PRNTase), and methyltransferase (MTase) domains. Bent arrows and red vertical lines indicate transcription initiation and polyadenylation/termination signals, respectively. (B) A RABV particle contains a ribonucleoprotein (RNP), which is composed of the genome and the N, P, and L proteins. The genome is wrapped with the N proteins to form a nucleocapsid (N-RNA), which serves as a template for RNA synthesis. The L protein interacts with its cofactor P protein to form an RdRp complex (L-P). The RNP is covered with the M proteins, and further enveloped by a lipid bilayer, which is studded with the G proteins.

transcription and replication (called N-RNA template) (Fig. 1B). Each N protomer encapsidates nine nucleotides of RNA (Albertini et al., 2006), suggesting that approximately 1300 N proteins are associated with a single RABV genome. RNA-dependent RNA polymerase (RdRp) complexes composed of the L protein (2127 amino acids) and its co-factor P protein (297 amino acids) interact with the N-RNA template to form a ribonucleoprotein (RNP) complex, which acts as a transcriptional machinery. In a virus particle, a bullet-shaped RNP complex is embedded in a matrix layer comprising the M proteins (202 amino acids) to form a skeleton-like structure, and further enclosed by a lipid bilayer derived from host cell plasma membrane (Riedel et al., 2019). The M protein mediates virus assembly and release by its direct interactions with the RNP and envelope (Mebatsion et al., 1999). The viral envelope is studded with the G proteins (505 amino acids, an integral transmembrane glycoprotein), which is critical for virus attachment and cell entry. For VSV, copy numbers of the N, P, M, G, and L proteins within a virion were estimated to be 1200, 500, 1800, 1200, and 50, respectively (Thomas et al., 1985). Typical RABV particles with approximately 80–90 nm in diameter and 180–220 in length represent a bullet-shape with conical and flat ends (Guichard et al., 2011; Riedel et al., 2019).

Transmission, life cycle, and pathogenesis

The major route of RABV transmission to humans is exposure of local tissues (e.g., muscle) to saliva from infected animals through bite wounds (Fig. 2A). After amplification of RABV in muscle cells, RABV infects motor neurons at neuromuscular junctions (Harrison and Murphy, 1978; Lentz et al., 1982; Burrage et al., 1985; Tsiang et al., 1986; Charlton et al., 1997; Yamaoka et al., 2013), where neuronal and muscular cells communicate each other via electrical signals. Alternatively, RABV may directly enter axon terminals of neurons without local replication in muscle cells (Coulon et al., 1989; Shankar et al., 1991). RABV also uses sensory neurons to travel to the CNS (Lycke and Tsiang, 1987; Coulon et al., 1989; Velandia-Romero et al., 2013).

Uptake of RABV into neurons at axon terminals is mediated by receptor binding followed by clathrin-dependent endocytosis (Superti et al., 1984; Lewis et al., 2000; Piccinotti et al., 2013; Piccinotti and Whelan, 2016). The RABV G protein plays critical roles in virus attachment and cell entry. The RABV G protein is composed of an N-terminal signal peptide, ectodomain with three subdomains [central domain (CD), pleckstrin homology domain (PHD), and fusion domain (FD)], transmembrane domain, and C-terminal cytoplasmic domain (Hellert et al., 2020; Yang et al., 2020) (Fig. 3A). A mature form of the G protein lacking the signal peptide is N-glycosylated at aspartate residues (e.g., D37, D319) within the ectodomain (Shakin-Eshleman et al., 1992; Shakin-Eshleman et al., 1993; Yamada et al., 2012, 2013), and is present as a membrane-anchored trimer (Whitt et al., 1991; Gaudin et al., 1992). The RABV G protein serves as not only a major antigen for the host immune system but also a key determinant of viral pathogenesis (reviewed in Lafron, 2016).

RABV may utilize several cell surface molecules as the G-protein-mediated attachment and/or entry receptors to infect muscular or neuronal cells. These cellular receptor candidates include nicotinic acetylcholine receptor (nAChR) (Lentz et al., 1982, 1984,

Fig. 2 Invasion of the central nervous system with RABV. (A) RABV is transmitted to humans by bites from rabid dogs or wild animals (e.g., bats, raccoons, skunks, foxes) through their saliva. RABV travels from peripheral muscle tissues to the central nervous system (the spinal cord followed by the brain) through the peripheral nervous system. (B) After replication of RABV in muscle cells, RABV enters motor neurons at neuromuscular junctions, and moves using the microtubule-dependent retrograde axonal transport system to their cell bodies, where viral genome transcription and replication occur. Transsynaptic retrograde transmission of RABV between neurons leads to invasion of the central nervous system.

1987; Lentz, 1990; Baer et al., 1990; Gastka et al., 1996; Kumar et al., 2007), neuronal cell adhesion molecule (NCAM or CD56, a member of the immunoglobulin superfamily) (Thoulouze et al., 1998), p75 neurotrophin receptor (p75NTR or CD27, a member of the tumor necrosis factor receptor superfamily) (Tuffereau et al., 1998; Langevin et al., 2002), metabotropic glutamate receptor subtype 2 (mGluR2, a member of the G protein-coupled receptor family) (Wang et al., 2018), heparan sulfate proteoglycans (Sasaki et al., 2018), integrin $\beta 1$ (Shuai et al., 2020), and carbohydrates (Superti et al., 1984; Conti et al., 1986). Different subtypes of nAChR are expressed on both pre- and post-synaptic membranes at neuromuscular junctions (reviewed in Hurst et al., 2013). Although α -bungarotoxin (a snake venom neurotoxin)-sensitive muscle-type nAChR is believed to serve as a G-receptor on muscle cells at neuromuscular junctions (Lentz et al., 1982; Tsiang et al., 1986), α -bungarotoxin-insensitive neuron-type nAChR may also have an affinity to the G protein (Lentz, 1990). However, the precise roles of these cellular receptor candidates in infection of muscular or neuronal cells with RABV still remain controversial and poorly understood (reviewed in Belot et al., 2019; Guo et al., 2019).

Internalized RABV within endocytic vesicles is transported in axons to their cell bodies via axonal dynein in a microtubule-dependent manner (Tsiang, 1979; Lycke and Tsiang, 1987; Klingenstein et al., 2008; Gluska et al., 2014; Piccinotti and Whelan, 2016) (Fig. 2B). Pseudotyping of lentiviruses or VSV with the RABV G protein confers infectivity to neurons and retrograde axonal transport ability on these viruses (Mazarakis et al., 2001; Beier et al., 2013; Hislop et al., 2014), indicating that the RABV G protein is a determinant of RABV neurotropism. Some of the receptor candidates, such as p75NTR, NCAM, and nAChR, are known to be co-transported with endocytic vesicles containing RABV or HIV pseudotyped with the RABV G protein along axons (Gluska et al., 2014; Hislop et al., 2014). In cell bodies, the endocytic vesicles containing RABV are routed to endosomes (Lewis et al., 1998; Gluska et al., 2014; Piccinotti and Whelan, 2016).

Once the endosomal lumen is acidified ($< \text{pH } 6.2$) during endosomal maturation, low-pH-dependent fusion between the viral and cellular membranes occurs prior to fusion of late endosomes with lysosomes (Fig. 4) (Whitt et al., 1991; Gaudin et al., 1991, 1993). During the fusion process, a structural rearrangement in the ectodomain of the RABV G protein in response to low pH repositions hydrophobic fusion loops in the fusion domain toward target cellular membranes (Fig. 3B), leading to membrane fusion (Gaudin et al., 1993; Hellert et al., 2020; Yang et al., 2020). In VSV, the membrane fusion and RNP release into the cytoplasm are separate events. First, the viral membrane preferentially fuses with intraluminal vesicles in endosomal intermediates, called endosomal carrier vesicles or multivesicular bodies, derived from early endosomes, resulting in uncoating of viral RNPs into the intraluminal vesicles (Le Blanc et al., 2005). Then, viral RNPs in intraluminal vesicles are delivered to late endosomes via endosomal carrier vesicles and subsequently released into the cytoplasm by back-fusion of the intraluminal vesicles with late-endosomal membranes, which is mediated by the late endosomal lipid lysobisphosphatidic acid and its binding protein, Alix (Le Blanc et al., 2005).

Fig. 3 Structure of the RABV G protein. (A) The domain organization of the RABV G protein is schematically represented. The N-terminal signal peptide (SP) is removed by signal peptidase (SPase). The ectodomain is composed of the central domain (CD), pleckstrin homology domain (PHD), and fusion domain (FD). The C-terminal part consists of the transmembrane domain (TMD) and cytoplasmic domain. The positions of a proposed binding site for nicotinic acetylcholine receptor (nAChR), N-glycosylation sites (N37, N319), and disulfide bridges between cysteine residues are indicated. Numbers indicate the positions of amino acid residues beginning and ending the domains/subdomains. (B) The crystal structures of the ectodomain of the RABV G protein at basic (PDB id: 6LGX) and acidic (PDB id: 6LGW) pH are shown as ribbon models. All structural images were generated with the UCSF Chimera program (Pettersen et al., 2004).

After releasing RNPs into the cytoplasm, RABV genome transcription and replication take place in membrane-less replication compartments (called Negri bodies) (Fig. 4) (Lahaye et al., 2009, 2012; Nikolic et al., 2016, 2017). Negri bodies were originally discovered as cytoplasmic inclusion bodies in neuronal cells of RABV-infected animals by Adelchi Negri in 1903 (reviewed in Kristensson et al., 1996; Nevers et al., 2020). Negri bodies exhibit dynamic liquid-like properties and are formed with multivalent weak interactions between viral replication components (e.g., N, P, and RNA) leading to their liquid-liquid phase separation from the cytosol (Nikolic et al., 2017). Negri bodies contain not only the RABV N, P, L proteins, genome, anti-genome, and mRNAs, but also host proteins, such as HSP70 and focal adhesion kinase (FAK), which positively regulate viral replication (Lahaye et al., 2009, 2012; Fouquet et al., 2015). Newly assembled RNPs are released from Negri bodies and move along microtubules to virus assembly sites (Nikolic et al., 2017).

Transsynaptic retrograde transmission of RABV between neurons leads to RABV invasion of the spinal cord followed by systematic infection of the entire brain leading to the acute progressive neurological disease (Coulon et al., 1989; Astic et al., 1993; Wickersham et al., 2007; Ugolini, 2011). Furthermore, RABV is known to spread in sensory neurons transsynaptically in the anterograde direction (Zampieri et al., 2014), suggesting that the anterograde transport of RABV is involved in centrifugal RABV spread to peripheral tissues. Enveloped RABV particles or viral RNPs are transported in axons of peripheral neurons such as sensory neurons in dorsal root ganglion in both the retrograde and anterograde directions (Lycke and Tsiang, 1987; Tsiang et al., 1989; Bauer et al., 2014). The RABV G protein is essential for transsynaptic transmission in both the directions (Etessami et al., 2000; Yan et al., 2002; Zampieri et al., 2014; Bauer et al., 2014). RABV is transported to salivary glands via the facial nerve and excreted in the saliva to further transmit to other animals or humans (Boonsriroj et al., 2016).

Pathogenic strains of RABV do not cause significant histopathological changes, inflammation, or neuronal cell death in the CNS of infected animals or humans, but induces disappearance of rough endoplasmic reticulum (ER) and ribosomes, mitochondrial dysfunction leading to oxidative stress, and beading/swelling and fragmentation of the dendrites and axons in infected neurons (Li et al., 2005a, b; Scott et al., 2008; Jackson et al., 2010; Alandijany et al., 2013; Kammouni et al., 2017), which may disrupt neuronal

Fig. 4 Life cycle of rhabdoviruses. Rhabdoviruses attach to receptors on the host cell surface by the G protein and enter host cells by clathrin-dependent endocytosis. Viral RNPs are released from late endosomes into the cytoplasm through a stepwise membrane fusion/uncoating process mediated at low pH. Viral transcription and replication occur in membrane-less replication compartments (called Negri bodies for RABV). For transcription, the RdRp (L–P) complex sequentially transcribes the *leader* region (*Le*) and *N*, *P*, *M*, *G*, and *L* genes on the negative-strand RNA genome in the N–RNA complex into the leader RNA (LeRNA) and monocistronic mRNAs with the 5′-cap 1 structure and 3′-poly(A) tail. For replication, the RdRp complex copies the genome into the positive-strand anti-genome, which is in turn used as a template to generate progeny genomes. A complex between the RNA-free N protein and P protein (N⁰–P) is required for encapsidation of these replication products. The M protein mediates the assembly of progeny RNPs and the G proteins into virus particles at the plasma membrane. Finally, viruses are budded from infected cells.

networks and/or other neuronal functions leading to neurological disorders in the late stage of infection. The G proteins of pathogenic and attenuated RABV strains interact with different cellular partners, microtubule-associated serine-threonine kinases 1 and 2 (MAST1 and MAST2) and non-receptor protein tyrosine phosphatase 4 (PTPN4) via slightly different PDZ-binding sites in their C-terminal cytoplasmic domain to promote markedly different outcomes, neuronal survival and apoptosis, respectively (Prehaud et al., 2010; Terrien et al., 2012). The neuronal survival, rather than death, phenotype of RABV strains is associated with their virulence in infected hosts. There are two types of rabies: encephalitic (furious) and paralytic (dumb) (Fooks et al., 2014, 2017). Patients with encephalitic rabies suffer hypersalivation, hydrophobia, aggressiveness, and agitation followed by coma, and die from respiratory failure or cardiac arrest. Patients with paralytic rabies have muscle spasms followed by paralysis and fall into a coma prior to death.

Transcription, replication, and translation

The RABV genome and anti-genome are wrapped with the N proteins during replication to form unique N–RNA templates for RNA synthesis. The N- and C-terminal domains (NTD and CTD) of the N protein are orientated in an angled conformation to form an RNA-binding groove (Fig. 5) (Albertini et al., 2006; Green et al., 2006), in which basic amino acid residues recognizes the phosphate backbone of 9-nt RNA. In the N–RNA complex, each N subunit interacts with neighboring N subunits via N-terminal arm and C-terminal loop structures extended from NTD and CTD, respectively (Albertini et al., 2006; Green et al., 2006). In VSV, the N-arm and C-loop structures and phosphate-binding basic amino acid residues were shown to be required for the formation of the functional N–RNA template (Zhang et al., 2008; Rainsford et al., 2010). In RABV particles, the N–RNA complex is tightly coiled into a bullet-shaped structure with an outer diameter of 56–74 (average 67) nm at the cylindrical trunk (Riedel et al., 2019). The trunk and

Fig. 5 Structure of the RABV N protein. (A) The RABV N protein is composed of the N- and C-terminal domains (NTD and CTD, respectively) with an arm-like (N-arm) and loop (C-loop) structures, respectively. A proposed binding site for the P protein is indicated by a dashed line. A phosphorylation site (S389) is labeled. (B) The crystal structure of a dimer of the RABV N subunits complexed with 18-mer of RNA (part of the undecameric N-RNA complex, PDB id: 2GTT) is represented as a ribbon model. The NTD and CTD of a subunit (left) are colored red and pink, respectively, whereas those of another subunit (right) are colored blue and light blue, respectively.

conical end of the N-RNA complex consist of 14–24 (average 18) and 1–7 helical turns, respectively (Riedel et al., 2019). A serine residue at position 389 (S389) of the RABV N protein is phosphorylated by cellular casein kinase II, resulting in efficient transcription and replication (Wu et al., 2002, 2003). As in the case of the VSV (Green and Luo, 2009), the C-loop of two adjacent N subunits in the RABV N-RNA complex may provide a binding site for the C-terminal domain of the P protein (Ribeiro Ede Jr. et al., 2009).

The RABV P protein acts as a multifunctional adapter molecule for the L and N proteins during transcription and replication. The RABV P protein is an elongated dimeric protein with non-structured regions (Gerard et al., 2007, 2009) and is phosphorylated at serine residues (e.g., S63, S64, S162, S210, S271) with cellular kinases including protein kinase C (Gupta et al., 2000) (Fig. 6). The P protein is a noncatalytic subunit of the RdRp L protein. Early studies identified two independent regions (residues 1–19 and 40–100) of the RABV P protein as L-binding sites (Chenik et al., 1998; Castel et al., 2009). A recent cryo-electron microscopic (EM) analysis of the RABV L-P complex revealed that a region encompassing residues 51–87 is associated with discontinuous regions of the L protein (Horwitz et al., 2020). Although residues 11–50 of the RABV P protein are sufficient to stimulate an in vitro transcription activity of the L protein (Morin et al., 2017), this region was invisible in the cryo-EM structure (Horwitz et al., 2020). The C-terminal domain (CTD, residues 186–297) of the P protein in the RdRp complex is required to interact with the N-RNA complex (Mavrikis et al., 2004; Ribeiro Ede Jr. et al., 2009). During replication, the P protein forms a complex with an RNA-free N protein (called N⁰) to prevent non-specific binding of the N protein to cellular RNAs and brings the N⁰ protein to the replication site to specifically encapsidate newly synthesized viral genomic and anti-genomic RNAs (Peluso 1988; Peluso and Moyer, 1988; Masters and Banerjee, 1988; Gupta and Banerjee, 1997; Leyrat et al., 2011). Thus, the P protein functions as a chaperone for the N protein. In the RABV P protein, the N-terminal portion (residues 4–40) binds the N⁰ protein to form the N⁰-P complex (Mavrikis et al., 2003, 2006). A central region (residues 90–133) of the P protein serves as a dimerization domain (Ivanov et al., 2010). However, residues 65–175 of the RABV P protein including the dimerization domain and part of the L-binding site are dispensable for RABV transcription in host cells (Jacob et al., 2001). The RABV P protein also interacts with cellular dynein light chain 1 (DLC1, also called LC8, a subunit of the minus-end-directed microtubule motor dynein) (Jacob et al., 2000; Raux et al., 2000; Poisson et al., 2001) and FAK (Fouquet et al., 2015) via residues 139–151 (containing a DLC1-binding motif [K/R]xTQT) and 106–131, respectively. Both the host factors positively regulate RABV transcription and replication in host cells (Tan et al., 2007; Fouquet et al., 2015). The interaction of the P protein with DLC1 does not play any roles in microtubule-dependent axonal transport of RABV (Tan et al., 2007).

As reported for VSV (Emerson and Yu, 1975; De and Banerjee, 1984, 1985; Hunt and Hutchinson, 1993; Hercyk et al., 1988; Grdzlishvili et al., 2005; Li et al., 2005a, b; Ogino and Banerjee, 2007; Galloway and Wertz, 2008; Rahmeh et al., 2009; Morin et al., 2012), the RABV L protein may catalyzes all enzymatic reactions (RNA synthesis, mRNA capping, cap methylation, and

Fig. 6 Structure of the RABV P protein. (A) The RABV P protein possesses the N-terminal domain (NTD), dimerization domain (DD), and C-terminal domain (CTD), which serve as binding sites for the RNA-free N (N^0) protein, P itself, and N-RNA complex, respectively. The reported L-binding sites and L-stimulation domain are located within the N-terminal part of the P protein. Amino acid residues phosphorylated by cellular kinases (S63, S64, S162, S210, and S271) are labeled. The binding sites for focal adhesion kinase (FAK), dynein light chain 1 (DLC1), signal transducer and activator of transcription 1 (STAT1), and promyelocytic leukemia (PML) are marked. The locations of N- and C-terminal nuclear export signals (N-NES and C-NES) and nuclear localization signals (N-NLS and C-NLS) are indicated. P2–P5 are N-terminally truncated isoforms of the P proteins. Nuclear (N) and cytoplasmic (C) localization of the full-length P protein (P1) and isoforms (P2–P5) is indicated. (B) The RABV P protein exists as a dimer with two structured domains: the DD (two subunits colored orange and pale orange, PDB id: 3L32) and CTD (yellow and pale yellow, PDB id: 1VVI). Other regions in the dimer are depicted as cartoons. The structure of residues 51–87 of the P protein in the L–P complex is shown in Fig. 7B.

polyadenylation) for biosynthesis of viral RNAs. However, only its RNA synthesis and capping activities have so far been biochemically demonstrated (Ogino et al., 2016, 2019; Morin et al., 2017). Similar to the VSV L protein (Liang et al., 2015; Qiu et al., 2016; Ogino and Green 2019a), the RABV L protein is composed of multiple domains, such as N-terminal (NTD), RdRp, GDP polyribonucleotidyltransferase (PRNTase), connector (CD), methyltransferase (MTase), and C-terminal (CTD) domains (Fig. 7A and B). The NTD (residues 35–375) comprises two subdomains (NTD_I and NTD_{II}) and topologically resembles domains of segmented negative-strand and double-strand RNA viral RdRps (Qiu et al., 2016), such as the PA C-terminal domain (PA_C) of influenza viruses (He et al., 2008; Obayashi et al., 2008; Pflug et al., 2014; Reich et al., 2014; Hengrung et al., 2015), the PA_C-like domain of La Crosse orthobunyavirus (Gerlach et al., 2015), and λ 3 N-terminal domain of reovirus (Tao et al., 2002). The NTD includes amino acid residues that are conserved among NNS RNA viruses and critical for transcription (Qiu et al., 2016; Ogino and Green, 2019a, b). Similar to other RNA viral RdRps (Poch et al., 1990; O'Reilly and Kao, 1998; Bruenn, 2003; Lang et al., 2013; Ogino and Green, 2019a), the RABV RdRp domain (residues 376–946) is constituted by three subdomains, called fingers, palm, and thumb, and carries structural motifs A–F (Ogino and Green, 2019b). Motifs A and C in the palm subdomain of the RABV L protein contain universally conserved aspartate residues, D618 and D729, respectively, which are thought to be critical for two-metal dependent nucleotide polymerization (Steitz, 1998; Castro et al., 2009; Genna et al., 2016). D729 of the RABV L protein was experimentally confirmed as an essential residue for its RNA synthesis activity (Schnell and Conzelmann, 1995; Ogino et al., 2019).

Between the RdRp and PRNTase domains, there is a functionally unknown region (called “bridge” in this chapter). Although this region as well as the C-terminal part of the thumb subdomain containing a highly conserved GGx(11,12)Rx(3)D motif was originally predicted to be involved in mRNA capping as part of “CAP” domain (residues 880–1352 in the RABV L protein) (Liang et al., 2015; Horwitz et al., 2020), there is no experimental evidence to support this hypothesis. The bridge region may provide a scaffold for the PRNTase domain (Ogino and Green, 2019a) and also form a template exit channel for the RdRp domain similar to the RdRp bridge subdomain of the L protein of La Crosse virus (Arragain et al., 2020). In the RABV L protein, the bridge region ends

Fig. 7 Structure of the RABV L protein. (A) The RABV L protein is composed of the N-terminal (NTD, subdomains: NTD_I and NTD_{II}), RNA-dependent RNA polymerase (RdRp, subdomains: fingers, palm, and thumb), GDP polyribonucleotidyltransferase (PRNTase), connector (CD), methyltransferase (MTase), and C-terminal (CTD) domains. The RdRp domain is connected to the PRNTase domain via a functionally unknown region (called “Bridge” in this chapter). The originally reported conserved blocks I–VI (Poch et al., 1990) are marked above the diagram. The NTD contains the indicated amino acid sequence motifs ([–], negatively charged; [+], positively charged; ζ, hydrophilic; Ψ, aliphatic; Ω, aromatic; x any amino acids), in which residues essential for transcription are highlighted in bold. The positions of RdRp structural motifs A–F are labeled by red bold letters (Ogino and Green, 2019a). Motif F is located in a loop structure, called fingertips. The PRNTase domain contains PRNTase motifs A–E (green bold letters) and a priming-capping loop (orange). The MTase domain includes an S-adenosyl-L-methionine-binding motif (G[–]GxG) and nucleoside-2′-O-MTase motif (K-D-K-E). Discontinuous P-binding regions are indicated by cyan dashed lines. The binding site for dynein light chain 1 (DLC1) is located at the C-terminal end of the bridge region. (B) Two views of the cryo-EM structure of the RABV L protein complexed with a fragment of the P protein (residues 1–91) (PDB id: 6UEB) are shown. The domains/subdomains of the L protein are colored as in (A). Residues 51–87 and five unassigned residues in the P fragment are colored dark cyan. (C) The structure of the RABV PRNTase domain (green) and part of the RdRp palm subdomain (red) are shown as ribbon models. The positions of PRNTase motifs A–E are labeled by circled green letters. The priming-capping loop is shown in orange with a priming amino acid residue (W1180) and TxΨ motif (T1174–x-L1176). Key amino acid residues (stick models) required for catalyzing the PRNTase activity or maintaining the PRNTase domain structure are colored cornflower blue. The N² position (marked by a red arrowhead) of H1241 in PRNTase motif D serves as a covalent pre-mRNA attachment site during the unconventional capping reaction. There are two binding sites for Zn²⁺ ions (gray spheres). The locations of catalytic aspartate residues, D618 and D729, within RdRp motifs A and C (denoted by circled red letters), respectively, are indicated.

with the DLC1 binding motif (residues 1079–1083) (Bauer et al., 2015) and is connected to the PRNTase domain via a highly diversified loop structure. The DLC1 binding motif in the RABV L protein is required for efficient transcription (Bauer et al., 2015) similar to the DLC1 binding motif in the P protein (Tan et al., 2007). The DLC1 binding motif or similar sequence is present in the L proteins of lyssaviruses, but not other rhabdoviruses, such as VSV. The RABV L protein induces acetylation of α -tubulin with the DLC1 binding motif, leading to microtubule bundling in cells overexpressing the RABV L protein alone (Bauer et al., 2015). At present, the roles of binding of the L protein to dynein and the L-mediated microtubule reorganization in viral replication, transport, and/or pathogenesis in infected cells remain unclear.

The PRNTase domain (residues 1093–1349) is conserved among NNS RNA viruses and includes five collinear sequence elements, Rx(3)Wx(3–8)ΦxGxζx(P/A) (motif A), (Y/W)ΦGSxT (motif B), W (motif C), HR (motif D), and ζxxΦx(F/Y)QxxΦ (motif E) (Φ, hydrophobic; ζ, hydrophilic amino acids) (Fig. 7C) (Ogino and Banerjee, 2011a, b; Neubauer et al., 2016; Ogino and Green, 2019a). In the RABV L protein, G1112 (motif A), T1170 (motif B), W1201 (motif C), H1241 (motif D), R1242 (motif D), F1285 (motif E), and Q1286 (motif E) were identified as critical for mRNA capping (Ogino et al., 2016). The PRNTase domain has a large loop structure, called priming-capping loop (Ogino et al., 2019), which is extended toward the RdRp active site in the apo-structure of the L protein complexed with a fragment of the P protein (Horwitz et al., 2020) and plays dual roles in transcription initiation and mRNA capping (Ogino et al., 2019). The PRNTase domain contains two Zn²⁺ ion binding elements (C1093–E1120–C1317–C1320 and C1132–C1134–H1312–H1314) (Horwitz et al., 2020), which may be essential for the structural integrity of the PRNTase domain.

The MTase domain (residues 1640–1920) includes a typical S-adenosyl-L-methionine (SAM)-dependent MTase fold with a SAM binding motif G[–]GxG ([–], negatively charged amino acids, residues 1704–1708) and also possesses a nucleoside-2′-O-MTase motif (K-D-K-E catalytic tetrad, K1685–D1797–K1829–E1867) (Bujnicki and Rychlewski, 2002). In VSV, the MTase domain was

suggested to catalyze methylation of the mRNA cap structure at the ribose-2'-O and guanine-N⁷ positions (Hercyk et al., 1988; Grdzlishvili et al., 2005; Li et al., 2005a, b, 2006; Rahmeh et al., 2009). The functions of CD (residues 1377–1615) and CTD (residues 1929–2107) are poorly understood. Although previous studies suggested that the RABV P protein is associated with the C-terminal part of the L protein (Chenik et al., 1998; Castel et al., 2009), the recent cryo-EM study (Horwitz et al., 2020) revealed that one of the L-binding regions (residues 51–87) contacts with three discontinuous regions located in the RdRp, CD, and CTD of the L protein. Similarly, the VSV P protein interacts with the RdRp, CD, and CTD of the VSV L protein (Jenni et al., 2020; Gould et al., 2020). The VSV L mutants with a particular amino acid substitution in the CD (F1488S) (Hunt and Hutchinson, 1993; Galloway and Wertz, 2008) or MTase domain (D1762E, K1651A) (Galloway and Wertz, 2008; Li et al., 2009) are known to produce mRNAs with an extra-long poly(A) tail, suggesting that these C-terminal domains are involved in determining the length of poly(A) tails.

The 3'- and 5'-terminal non-coding regions of the genome are called *leader* (*Le*, 58 nt) and *trailer* (*Tr*, 70 nt), respectively (Fig. 8A). The 3'-terminal parts of the genomic *Le* and anti-genomic *Tr* act as promoters for synthesis of the anti-genomic and genomic RNAs, respectively (Conzelmann and Schnell, 1994; Schnell et al., 1994; Finke and Conzelmann, 1997; Morin et al., 2017; Ogino et al., 2019). The promoter strength of anti-genomic *Tr* is approximately 50-fold higher than that of genomic *Le*, resulting in production of a larger amount of the genomic RNA and, thereby, its efficient packaging into virions (Finke and Conzelmann, 1997). The genes of RABV begin and end with conserved sequences, called gene-start (3'-UUUGURRDGA-5'; R = G or A, D = A, G, or U) and gene-end (3'-ACUUUUUUUU-5'), respectively, (Ogino and Green, 2019b) and are tandemly linked by an intergenic region of variable lengths (2–24 nt) (Tordo et al., 1986b; Conzelmann et al., 1990). During transcription, the gene-start and gene-end sequences serve as transcription initiation and polyadenylation/termination signals, respectively (Conzelmann and Schnell, 1994; Schnell et al., 1994; Mebatsion et al., 1996b; Barr et al., 1997; Stillman and Whitt, 1999; Ogino et al., 2019).

According to the “single entry, stop-start transcription” model suggested from in vitro studies on VSV transcription (Abraham and Banerjee, 1976; Ball and White, 1976; Testa et al., 1980; Emerson, 1982), the RABV RdRp complex enters from the 3'-terminal of the genomic *Le* promoter and carries out sequential synthesis of a short non-coding RNA (55–58 nt), called the leader RNA (LeRNA), (Kurilla et al., 1984) followed by monocistronic *N*, *P*, *M*, *G*, and *L* mRNAs (Flamand and Delagneau, 1978; Coslett et al., 1980; Holloway and Obijeski, 1980) (Fig. 8A). As in the case of VSV (Colonno and Banerjee, 1976), the RABV LeRNA synthesis is initiated at the 3'-end of the genome and terminated just before the RdRp reaches the *N* gene-start sequence (Kurilla et al., 1984). LeRNA does not undergo 5'-capping or 3'-polyadenylation. After the LeRNA synthesis, the same RdRp repeats mRNA synthesis cycles including reinitiation and termination steps at each gene junction to sequentially transcribes the internal genes. However, since the efficiency of transcription reinitiation at each gene-start sequence is about 70% or lower, the rhabdoviral RdRps generate a gradient in mRNA abundance in the following order: *N* > *P* > *M* > *G* > *L* (Abraham and Banerjee, 1976; Ball and White, 1976; Iverson and Rose, 1981; Flamand and Delagneau, 1978; Finke et al., 2000). After releasing polyadenylated mRNA at a gene-end sequence, the RdRp scans an intergenic region until a downstream gene-start sequence is encountered. In RABV, longer intergenic regions (*G/L*, 24 nt > *P/M* and *M/G*, 5 nt > *N/P*, 2 nt) are known to significantly downregulate the production of mRNAs from downstream genes (Finke et al., 2000). In contrast, all the intergenic regions of VSV (Indiana) consist of 2 nt (Rose, 1980), achieving nearly constant reinitiation efficiencies (~70%) at the gene junctions.

RABV mRNAs produced in infected cells possess 3'-poly(A) tail of 100–250 nt (Holloway and Obijeski, 1980), and are believed to have a methylated cap structure, such as m⁷G(5')ppp(5')Am- (cap 1), m⁷G(5')ppp(5')AmpAm- (cap 2), and m⁷G(5')ppp(5')m⁶Ampm⁶Am- (m⁷G, N⁷-methylguanosine; Am, 2'-O-methyladenosine; m⁶Am, N⁶,2'-O-dimethyladenosine) at their 5'-termini as observed in VSV mRNAs (Abraham et al., 1975a; Moyer et al., 1975; Moyer and Banerjee, 1976). Detergent disrupted VSV particles, purified RNPs, or reconstituted RNPs with the N-RNA and recombinant RdRp complexes are known to produce mRNAs with the cap 1 structure in the presence of SAM in vitro (Abraham et al., 1975a; Testa and Banerjee, 1977; Ogino, 2013), indicating that VSV particles contain all enzymes required for the formation of the cap 1 structure. However, it remains challenging to characterize RABV-associated mRNA-producing enzymes or identify their products, especially 5'-terminal structures, due to extremely low mRNA synthesis activities of purified RABV particles (Villareal and Holland, 1974; Kawai, 1977; Flamand et al., 1978).

Recent development of in vitro RNA synthesis and capping assay systems with a recombinant form of the RABV L protein (Ogino et al., 2016; Morin et al., 2017; Ogino et al., 2019) allowed us to elucidate the mechanisms of RABV RNA biosynthesis at molecular levels. To synthesize LeRNA and mRNAs from the genome, the RdRp needs to carry out transcription initiation at the 3'-terminal *Le*-start sequence (3'-UGCGAA) and internal gene-start sequences, respectively (Fig. 8A). In vertebrate and/or arthropod rhabdoviruses including RABV and VSV, the priming-capping loop extended from the PRNTase domain contains a highly conserved tryptophan residue (W1180 for RABV) and TxΨ motif (Ψ, aliphatic amino acids, T1174-x-L1176 for RABV) (Ogino et al., 2019). The in vitro transcription system with artificial oligo-RNA templates revealed that the W residue is required for terminal de novo initiation to generate a dinucleotide pppApC RNA at the 3'-terminal U₁G₂ sequence (Ogino et al., 2019). Based on structural models of the VSV and RABV transcription initiation L complexes with ATP (initiator nucleotide), CTP (incoming nucleotide), and a model template (3'-UGCG for RABV or 3'-UGCU for VSV) (Ogino et al., 2019; Ogino and Green, 2019b) (Model Archive id: ma-5 k432 and ma-uqibu), the adenine base of ATP was suggested to be sandwiched between the indole group of the W residue on the loop and the cytosine base of CTP via π -stacking interactions to form a stable initiation complex on the 3'-terminal UG sequence (Fig. 8B). The W residue is not essential for internal de novo initiation from the gene-start sequence to synthesize pppApA-started RNAs, their chain elongation, or RNA capping (Ogino et al., 2019). In contrast, the TxΨ motif is required for RNA capping, but not for transcription initiation either from the 3'-terminal *Le*-start or from the internal gene-start sequence (Ogino et al., 2019). These findings suggest that the priming-capping loop is displaced from the RdRp active site after terminal initiation to conduct LeRNA chain elongation followed by internal de novo initiation for *N* mRNA synthesis and undergoes a further structural rearrangement to

Fig. 8 RNA synthesis and processing by the RABV L protein. (A) The negative-strand RABV genome has the 3'- and 5'-terminal *leader* (Le, 58 nt) and *trailer* (Tr, 70 nt) regions, respectively (upper). The genes are tandemly connected via intergenic regions with the indicated lengths. The 3'-terminal part of the genome encapsidated with the N proteins (pale red) is illustrated with the *Le*-start, *N* gene-start, *N* gene-end, intergenic, and *P* gene-start sequences (lower). The RdRp complex composed of the L protein with the RdRp (pale blue), PRNTase (pale green), and MTase (pale orange) domains and the P protein (pale yellow) is schematically delineated. Circled red "D" letters in the RdRp domain indicate D618 and D729. Circled blue "T", "H", and "R" letters in the PRNTase domain indicate T1170, H1241, and R1242, respectively. Circled blue "T" and "L" (TxY motif) and orange "W" letters on the priming-capping loop (orange) indicate T1174, L1176, and W1180, respectively. pppA, pppC, and SAM indicate ATP, CTP, and S-adenosyl-L-methionine, respectively. The RdRp complex enters from the 3'-end of the genome to synthesize the leader RNA (LeRNA) and then transcribes the *N* gene into *N* mRNA with the 5'-cap 1 structure and 3'-poly(A) tail. The priming-capping loop mediates terminal initiation at the *Le*-start sequence to produce LeRNA and pre-mRNA capping at an early stage of mRNA chain elongation using W1180 and the TxY motif, respectively. In contrast, the loop is not required to initiate mRNA synthesis at the gene-start sequence. The cap structure is methylated with the MTase domain during transcription. Finally, the RdRp adds a poly(A) tail to the 3'-end of *N* mRNA by transcriptional slippage at the U7 sequence in the gene-end sequence. After releasing mature *N* mRNA, the RdRp reinitiates transcription at the *P* gene-start sequence. (B) A predicted conformation of the priming-capping loop in a modeled terminal initiation complex of the RABV L protein (Model Archive id: ma-ujibu) is shown with a 3'-UG-ended model RNA (genome), ATP (initiator nucleotide), CTP (incoming nucleotide), and part of the RdRp palm subdomain. Key amino acid residues are shown as in Fig. 7C. The loop may be retracted after terminal de novo initiation (curved dashed arrow). (C and D) The pathway of the cap formation by rhabdoviruses (C) are compared with that by eukaryotes (D). GTP, RNA, and SAM (substrates) are shown in red, blue, and green, respectively. Moieties of enzymatic products are colored in red, blue, and green based on their origins (GTP, RNA, and SAM, respectively). The positions of phosphate groups in the triphosphate (ppp) on the substrates are labeled by α , β , and γ . P_i, PP_i, and SAH indicate inorganic phosphate, inorganic pyrophosphate, and S-adenosyl-L-homocysteine, respectively. In rhabdoviruses (C), the cap core structure is formed with guanosine 5'-triphosphatase (GTPase) followed by GDP polyribonucleotidyltransferase (PRNTase, shown by "L") and methylated with mRNA (nucleoside₁-2'-*O*)-methyltransferase (N₁-2'-*O*-MTase) followed by mRNA (guanine-*N*⁷)-methyltransferase (G-*N*⁷-MTase) to form the cap 1 structure (m⁷GpppAm, chemical structure shown at the bottom). In higher eukaryotes (D), the cap core structure is generated with RNA 5'-triphosphatase (RTPase) followed by mRNA guanylyltransferase (GTase, shown by "E") and methylated with G-*N*⁷-MTase followed by N₁-2'-*O*-MTase to yield the cap 1 structure (m⁷GpppNm, N: any nucleotide).

mediate pre-mRNA capping during mRNA chain elongation (Ogino et al., 2019). In cryo-EM structures of non-transcribing L proteins of human respiratory syncytial virus (Gilman et al., 2019), human metapneumovirus (*Pneumoviridae*) (Pan et al., 2020), and parainfluenza virus 5 (*Paramyxoviridae*) (Abdella et al., 2020), which are complexed with their cognate P proteins, their counterparts of the rhabdoviral priming-capping loop are associated with or close to their putative PRNTase active sites, but not extended into their RdRp active sites. These observations suggest that the loop structures are flexible and can be rearranged into different conformations during the dynamic stop-start transcription cycle.

Rhabdoviruses, such as VSV (Abraham et al., 1975a, b; Ogino and Banerjee, 2007; Ogino et al., 2010), Chandipura virus (Ogino and Banerjee, 2010), and RABV (Ogino et al., 2016), employ an unconventional mechanism of mRNA capping (Fig. 8C). First, a guanosine 5'-triphosphatase (GTPase) activity associated with the L protein removes the γ -phosphate of GTP to yield GDP, which in turn serves as an acceptor substrate in the subsequent PRNTase reaction (Ogino and Banerjee, 2007, 2008; Ogino et al., 2016). Then, a lone pair of electrons at the $N^{\epsilon 2}$ position of the highly conserved histidine residue (H1227 for VSV, H1241 for RABV) in motif D (also called HR motif) of the L PRNTase domain nucleophilically attacks the α -phosphorus in the 5'-triphosphate group of pre-mRNA, but not LeRNA, to form a covalent enzyme-substrate intermediate composed of the L protein and 5'-monophosphorylated RNA (L-pRNA) (Ogino and Banerjee, 2007; Ogino et al., 2010; Ogino, 2013). In the L-pRNA intermediate, the 5'-monophosphate end of RNA is linked to the $N^{\epsilon 2}$ atom of the histidine residue via a phosphoamide bond (Ogino and Banerjee, 2007; Ogino et al., 2010). The intermediate subsequently transfers pRNA to GDP to form a cap core structure, GpppA, on the 5'-end of pre-mRNA (Ogino et al., 2010; Ogino and Ogino 2017). Therefore, origins of the phosphate groups forming the triphosphate bridge of the rhabdoviral cap structure are the α - and β -phosphates of GTP and the α -phosphate of the initiator ATP. Consistent with conserved lyssaviral (5'-AACABYHCU; B = C, G, or U; Y = U or C; H = A, C, or U) and vesiculoviral (5'-ARCAGNNNUMV; R = A or G, N = any nucleotide; M = A or C; V = A, C, or G) mRNA-start sequences (Ogino and Green, 2019b), the RABV and VSV PRNTase domains specifically cap 5'-triphosphorylated AACNN- and ARCNG-started RNAs (R = A or G), respectively (Ogino and Banerjee, 2007, 2008; Ogino et al., 2016). In contrast, it is well known that eukaryotic mRNA capping enzyme elicits a different set of enzymatic activities to form the cap core structure (GpppN) on cellular pre-mRNAs of any 5'-sequence (reviewed in Furuichi and Shatkin, 2000; Shuman, 2001; Ghosh and Lima, 2010) (Fig. 8D). In the first step, the RNA 5'-triphosphatase (RTPase) activity of eukaryotic mRNA capping enzyme removes the γ -phosphate of 5'-triphosphorylated RNA (pppRNA) to generate 5'-diphorylated RNA (ppRNA). In the second step, mRNA guanylyltransferase (GTase) reacts with GTP to form a covalent enzyme-GMP intermediate (E-pG) using a nucleophilic lysine residue in the conserved KxDG motif, and then transfers GMP from the intermediate to ppRNA to produce the 5'-cap structure on RNA.

In all known eukaryotic cells, the cap structure on cellular mRNAs is methylated by mRNA (guanine- N^7)-methyltransferase (G- N^7 -MTase) in the nucleus to generate the cap 0 structure, m^7 GpppN (Fig. 8D), which is required for mRNA stability and eukaryotic gene expression at various stages, such as mRNA splicing, transport, and translation (reviewed in Banerjee, 1980; Furuichi and Shatkin, 2000; Ramanathan et al., 2016). In higher eukaryotes, the cap 0 structure is further methylated by mRNA (nucleoside₁-2'-O)-methyltransferase (N_1 -2'-O-MTase) followed by N_2 -2'-O-MTase to produce the cap 1 structure, m^7 GpppN₁m, and the cap 2 structure, m^7 GpppN₁mpN₂m. For many viruses, the formation of the cap 1 structure on their mRNAs is critical to avoid anti-viral innate immune reactions triggered by cytosolic pattern recognition receptors [e.g., retinoic acid-inducible gene I (RIG-I)] that recognize RNAs with a 2'-hydroxyl group at the N_1 position as non-self RNAs (reviewed in Hyde and Diamond, 2015; Leung and Amarasinghe, 2016). In VSV, virion-associated MTases catalyze methylation of the cap core structure at the N_1 -2'-O position followed by the G- N^7 position into the cap 1 structure (Fig. 8C) (Testa and Banerjee, 1977, #216; Hammond and Lesnaw, 1987). Although the methylation reactions had been thought to be tightly coupled to mRNA synthesis for a long time (Banerjee, 1980), Rahmeh et al. (2009) reported that a recombinant form of the VSV L protein alone can methylate the cap core structure on exogenously added RNA substrates with the VSV N mRNA-start sequence in the following order: GpppA $\rightarrow$ GpppAm $\rightarrow$ m^7 GpppAm. The single MTase domain in the VSV L protein was suggested to catalyze the two cap methylation reactions (Grdzlishvili et al., 2005; Li et al., 2005a, b, 2006), whereas the two separate host enzymes conduct the individual methylation reactions to form the cap 1 structure on eukaryotic mRNAs. Methylation-defective mutations in the conserved motifs of the VSV MTase domain attenuate VSV (Grdzlishvili et al., 2005; Li et al., 2005a, b, 2006), whereas mutations of the RdRp or PRNTase active site are lethal to VSV (Ogino, 2014). So far, the enzymatic activities of the RABV MTase domain have not been characterized.

During replication, the RABV RdRp copies the genome into the anti-genome, which in turn serves as a template to produce progeny genomes (Fig. 4). Both the genome and anti-genome are encapsidated with newly synthesized N proteins, which may be co-replicationally supplied from the RNA-free N^0 -P complex (Peluso, 1988; Peluso and Moyer, 1988; Masters and Banerjee, 1988; Gupta and Banerjee, 1997). In the presence of the P protein, the N protein may selectively interact with the positive-strand LeRNA, resulting in its elongation into the full-length genome with concomitant nucleocapsid assembly (Blumberg et al., 1981, 1983; Yang et al., 1998). The RdRp ignores the genomic RNA signals for stop-start transcription during replication to synthesize the full-length anti-genome. In RABV, the M protein represses transcription, but enhances replication, thus suggesting that the M protein can switch the RNA synthesis mode from transcription to replication (Finke and Conzelmann, 2003; Finke et al., 2003).

The monocistronic mRNAs of rhabdoviruses are translated into the five proteins in a cap-dependent manner (Both et al., 1975a; Muthukrishnan et al., 1975). The N, P, M, and L proteins are produced on free ribosomes, whereas the G protein is generated on ER-bound ribosomes (Grubman et al., 1974; Both et al., 1975b; Morrison, 1975; Pennica et al., 1980). A precursor of the G protein is co-translationally cleaved after an N-terminal signal peptide sequence by signal peptidase within the ER lumen and further undergoes glycosylation in the ER and Golgi apparatus during its maturation (Hunt and Summers, 1976; Toneguzzo and Ghosh, 1977; Lingappa et al., 1978). In addition to the full-length RABV P protein (also called P1), its N-terminal truncated forms (called

P2–P5) are synthesized from RABV *P* mRNA using alternative in-frame AUG codons by leaky ribosomal scanning (Chenik et al., 1995) (Fig. 6). The M protein of RABV inhibits cap-dependent translation by interacting with eIF3h, a subunit of eukaryotic initiation factor 3 (Komarova et al., 2007). However, the role of the interaction between the RABV M protein and eIF3h in the regulation of cellular and/or viral translation during the course of infection is undefined.

Virus assembly and budding

RABV assembly and budding occur at the plasma membrane of infected cells at the late stage of infection (Fig. 4). The M protein plays central roles in these events. X-ray crystallography revealed that the M protein of rhabdoviruses, such as VSV (vesiculovirus) and Lagos bat virus (LBV, lyssavirus), is a small globular protein with an extended N-terminal segment (Gaudier et al., 2002; Graham et al., 2008). In the crystals, each M protein is associated with neighboring M proteins via their N-terminal segments and globular domains to form non-covalent linear polymers (Graham et al., 2008). Here, based on the structure of the LBV M protein, a structure of the RABV M protein was predicted using the SWISS-MODEL program (Waterhouse et al., 2018) (Fig. 9).

The M proteins cover the RNP by interacting with the N proteins and condense the RNP into a tightly coiled skeleton-like structure (Newcomb and Brown, 1981; Newcomb et al., 1982; Chong and Rose, 1994; Lyles et al., 1996; Mebatsion et al., 1999). The M proteins are self-assembled into higher order structures at lower salt concentrations (Gaudin et al., 1995, 1997). The M protein also interacts with cellular membranes (Chong and Rose, 1993, 1994; Gaudier et al., 2002) and the G protein (Lyles et al., 1992; Mebatsion et al., 1999; Nakahara et al., 1999) to facilitate virion assembly. The cytoplasmic tail of the G protein is required for its efficient incorporation into virus particles by binding to the M protein (Mebatsion et al., 1996a, 1999). Without the M protein, infectious RABV particles containing an RNP and the G proteins cannot be released from infected cells efficiently, and exhibit abnormal shapes, such as long rods (Mebatsion et al., 1999). In VSV-infected cells, the M and G proteins are accumulated in separate plasma membrane microdomains, and are finally assembled with the RNPs at budding sites (Swintek and Lyles 2008).

The VSV M protein has an intrinsic ability to assemble and release virus-like particles composed of the cellular plasma membrane and the M proteins when expressed in cells in the absence of other viral proteins (Li et al., 1993; Justice et al., 1995). The PPxY motif (a late-budding domain motif) in the N-terminal segments of the RABV and VSV M proteins interacts with the WW domains of cellular Nedd4 and/or Nedd4-like ubiquitin E3 ligases and is required for efficient budding (Harty et al., 1999; Craven et al., 1999; Jayakar et al., 2000; Irie et al., 2004; Wirblich et al., 2008), which may be mediated by the cellular ESCRT (endosomal sorting complexes required for transport) machinery (reviewed in Votteler and Sundquist, 2013). However, the detailed mechanisms of rhabdovirus budding are not fully understood.

Subversion of host immune responses

RABV has evolved strategies to subvert host innate immune reactions at various steps. In infected cells, viral RNAs are recognized by various cytosolic pattern recognition receptors, such as RIG-I-like receptors (RLRs, members of the DEAD-box RNA helicase family),

Fig. 9 Structure of the RABV M protein. (A) The schematic diagram of the RABV M protein is shown with putative binding sites for M itself and the G protein. The PPxY motif (a late-budding domain motif) in the N-terminal segment is essential for virus budding. (B) A three-dimensional structure of the RABV M protein (PV strain, GenBank id: M13215) was predicted with SWISS-MODEL (Waterhouse et al., 2018) using the structure of the M protein of Lagos bat virus (PDB id: 2W2S) as a template.

Fig. 10 Subversion of host innate immune responses by RABV. To evade the activation of RIG-I that recognizes viral RNA with a 5'-(p)pp-group or 2'-O-unmethylated cap structure (e.g., m⁷GpppA-, GpppA-), viral genomic and antigenomic RNAs with a 5'-(p)pp-end are wrapped with the N proteins, and the 5'-ends of viral mRNAs are modified into the cap 1 structure (m⁷GpppAm-) with the L protein. Association of 5'-(p)pp-ended LeRNA with cellular La protein may shield it from RIG-I. The RABV P protein inhibits IRF3-dependent RIG-I signaling at the step of IRF3 phosphorylation to abolish expression of type-I IFNs. The RABV P protein also represses both the IFNα/IFNβ- and IFNγ-mediated JAK/STAT signaling by inhibiting nuclear translocation of STAT1 and STAT2 and their target DNA binding. Furthermore, the RABV M protein inhibits JAK1 phosphorylation and nuclear translocation of STAT1. The formation of the cap 1 structure on viral mRNAs is required to avoid translation inhibition with IFIT1. The RABV P protein counteracts antiviral actions of PMLIII. For details and abbreviations, see text.

resulting in initiation of various immune responses (reviewed in [Rehwinkel and Gack, 2020](#)). Although RIG-I is essential to initiate antiviral responses against RABV, RABV efficiently inhibits RIG-I-dependent signaling with the P protein ([Fig. 10](#)) ([Hornung et al., 2006](#)). RIG-I senses N₁-2'-O-unmethylated double-strand and possibly single-strand RNAs bearing a 5'-(p)ppN₁-, GpppN₁-, or m⁷GpppN₁-end as non-self RNAs ([Hornung et al., 2006](#); [Pichlmair et al., 2006](#); [Goubau et al., 2014](#); [Schuberth-Wagner et al., 2015](#); [Devarkar et al., 2016](#); [Linehan et al., 2018](#); [Ren et al., 2019](#)). Thus, the formation of the cap 1 structure (m⁷GpppN₁m) on rhabdoviral mRNAs by the L protein ([Abraham et al., 1975a](#); [Ogino and Banerjee, 2007](#); [Rahmeh et al., 2009](#); [Ogino et al., 2016](#)) is required for their escape from RIG-I. Since the viral genomic/anti-genomic RNA and LeRNA have 5'-(p)pp-ends ([Hefti and Bishop, 1975](#); [Keene et al., 1979](#); [Colonno and Banerjee, 1976](#)), they may serve as ligands for RIG-I ([Hornung et al., 2006](#)). In infected cells, the viral genomic and anti-genomic RNAs are thought to be shielded from RIG-I by the N proteins ([Iseni et al., 1998](#); [Albertini et al., 2006](#); [Masatani et al., 2010, 2011](#)). In human respiratory syncytial virus-infected cells, cellular RNA binding protein La sequesters 5'-triphosphorylated LeRNA from RIG-I, evading RIG-I activation ([Bitko et al., 2008](#)). Similarly, LeRNAs of VSV and RABV are present as complexes with La in infected cells ([Kurilla and Keene, 1983](#); [Kurilla et al., 1984](#)), suggesting that rhabdoviruses use the same strategy as pneumoviruses to mask the potential RIG-I ligands.

Once RIG-I is activated by sensing viral RNAs, it undergoes a structural rearrangement to expose and oligomerize its caspase activation and recruitment domains (CARDs), leading to its interaction with mitochondrial antiviral-signaling protein (MAVS) ([Rehwinkel and Gack, 2020](#)). The activated MAVS signaling complex subsequently activates TANK binding kinase 1 (TBK1) and IκB kinase-ε (IKKε) to phosphorylate IFN regulatory factor 3 (IRF3) and IRF7. Phosphorylation of IRF3 and IRF7 promotes their dimerization and translocation into the nucleus, where these transcription factors induce expression of type I IFNs, such as IFNα and IFNβ. The RABV P protein inhibits the activation of IRF3 and IRF7 with its unstructured region including residues 176–186, thereby preventing the IFN production ([Rieder et al., 2011](#)). Furthermore, the RABV M protein inhibits NF-κB signaling by interacting with RelA/p43 (a p65/RelA variant belonging to the NF-κB family) to reduce IFNβ production ([Luco et al., 2012](#); [Ben Khalifa et al., 2016](#); [Besson et al., 2017](#)).

Type I IFNs are secreted from infected cells and interact with heterodimeric IFNα receptor composed of IFNAR1 and IFNAR2 on the cell surface (reviewed in [Wang et al., 2017](#); [Morris et al., 2018](#)). JAK1 and TYK2, members of the Janus kinase (JAK) family are associated with the cytoplasmic tails of the IFNAR2 and IFNAR1, respectively, and are activated by transphosphorylation upon

binding of type I IFN to the receptor. Activated JAK further phosphorylates the cytoplasmic tails of the IFN receptor, leading to recruitment and phosphorylation of signal transducer and activator of transcription 1 (STAT1) and STAT2. Phosphorylated STAT1-STAT2 heterodimer and STAT2 homodimer interact with IFN regulatory factor 9 (IRF9) to form complexes called IFN-stimulated gene factor 3 (ISGF3) and ISGF3-like complex, respectively, which are translocated into the nucleus to promote expression of interferon-stimulated genes (ISGs) by binding to IFN-stimulated response elements (ISREs) on their promoters. Similarly, type II IFN (IFN γ) is associated with IFN γ receptor composed of IFNGR1 and IFNGR2 to activate STAT1 via JAK1 and JAK2. The resulting phosphorylated STAT1 homodimer, called γ -activated factor (GAF), is transported into the nucleus to stimulate ISG expression by binding to γ -activated sequences (GASs).

The RABV P protein inhibits both the IFN α /IFN β - and IFN γ -mediated JAK/STAT signaling by retaining phosphorylated STAT1 and STAT2 in the cytoplasm and inhibiting their target DNA binding (Vidy et al., 2005; Brzozka et al., 2006; Vidy et al., 2007). The RABV P protein has N- and C-terminal nuclear export signals (NESs, residues 49–58 and 227–232) and nuclear localization signals (NLSS, residues 53–174, 211–214 and 260) to shuttle between the cytoplasm and nucleus (Pasdeloup et al., 2005; Moseley et al., 2007; Oksayan et al., 2012; Rowe et al., 2016). The N-terminal NES of the P protein is critical for its inhibitory activity against STAT1 nuclear translocation (Ito et al., 2010), suggesting that the P protein may form a complex with nuclear STAT1 to exclude it from the nucleus to the cytoplasm by the CRM1 nuclear export receptor. Among the P isoforms, P3–P5 are localized in the nucleus (Pasdeloup et al., 2005; Moseley et al., 2007; Oksayan et al., 2012; Rowe et al., 2016). Both the cytoplasmic (P1 and P2) and nuclear (P3–P5) forms of the P protein were suggested to be involved in its IFN antagonistic activities. Expression of these truncated forms of the RABV P protein is essential for viral IFN antagonism and replication in muscle cells, leading to viral neuroinvasiveness (Okada et al., 2016). The CTD of the RABV P protein contains discontinuous tyrosine-phosphorylated STAT-binding sites (Vidy et al., 2005; Brzozka et al., 2006; Hossain et al., 2019), which are required for viral IFN antagonism in infected cells as well as pathogenesis in brains of infected mice (Wiltzer et al., 2014). In addition, the CTD of P3 was reported to interact with both STAT1 and microtubules in the cytoplasm to inhibit STAT1 nuclear translocation by sequestering STAT1 on microtubules (Moseley et al., 2009; Brice et al., 2016). Furthermore, the RABV M protein binds JAK1 to inhibit its phosphorylation upon IFN stimulation, and also interacts with phosphorylated STAT1 to hamper its nuclear translocation cooperatively with the P protein (Sonthonnax et al., 2019). The RABV P protein also binds activated STAT3-STAT1 heterodimer, but not STAT3 homodimer, resulting in inhibition of gp130 cytokine receptor signaling (Lieu et al., 2013; Harrison et al., 2020).

In response to IFNs, expression of numerous ISG products including double-stranded RNA-activated protein kinase (PKR), RNase L, and Mx1 is induced to combat various viruses (reviewed in Schoggins, 2019). However, antiviral actions of individual ISG products against RABV and RABV strategies to counteract them have not been studied well. Promyelocytic leukemia (PML) protein, a member of the tripartite motif (TRIM) protein family, is one of ISGs and serves as a restriction factor against diverse viruses including VSV (Chelbi-Alix et al., 1998; Bonilla et al., 2002; El Asmi et al., 2014). Together with IFN-inducible Sp100 and other factors, PML forms subnuclear membrane-less structures, called PML nuclear bodies (NBs), which enhance expression of IFN β gene and ISGs and also repress some DNA viral gene expression directly (reviewed in Scherer and Stamminger, 2016). Many nuclear-replicating DNA viruses are known to antagonize one or more of PML-NB components with their viral proteins to counteract PML-NB-mediated anti-viral activities (Scherer and Stamminger, 2016). Although there are isoforms of PML (PML1 to PMLVIIb, produced by alternative splicing), only PMLIII and PMLIV have the ability to repress VSV replication by an as-yet-unknown mechanism (El Asmi et al., 2014). PMLIV also enhances IFN β production in an IRF3-dependent manner in response to VSV infection (El Asmi et al., 2014). For RABV, PMLIV, but not PMLIII, serves as a restriction factor and inhibits viral transcription and replication in an IFN-independent manner (Blondel et al., 2010). The C-terminal part (residues 223–297) of the RABV P protein directly interacts with PMLIII and sequesters it in the cytoplasm (Blondel et al., 2002), conferring resistance of RABV to PMLIII.

In RABV-infected cells, stress granules (SGs), membrane-less structures containing antiviral proteins, such as TIA-1, and RLRs (RIG-I and MDA5) are formed in a PKR-dependent manner. RABV escapes from antiviral actions of SGs by compartmentalizing viral replication machineries into separate membrane-less organelles (Negri bodies) (Nikolic et al., 2016, 2017). Furthermore, the formation of Negri bodies reduces innate immune responses by sequestering Toll-like receptor 3 (TLR3) (Menager et al., 2009), which senses viral double-strand RNAs in endosomes to induce production of type I IFNs and inflammatory cytokines through IRF3 and NF- κ B signaling pathways (reviewed in Lester and Li, 2014). Therefore, Negri bodies play critical roles not only in viral replication but also in innate immune escape in host cells.

Interferon induced protein with tetratricopeptide repeats 1 (IFIT1) interacts with 2'-O-unmethylated cap structures (e.g., GpppN₁, m⁷GpppN₁) on viral mRNAs and thereby abolishes their translation together with its related proteins, such as IFIT2 and IFIT3 (Daffis et al., 2010; Habjan et al., 2013; Kumar et al., 2014; Daugherty et al., 2016; Abbas et al., 2017; Fleith et al., 2018; Johnson et al., 2018). IFIT1 represses replication of positive strand RNA viruses (flavivirus, coronavirus) and DNA viruses (poxvirus) if their N₁-2'-O-MTase activities are defective (Daffis et al., 2010). Therefore, the formation of the fully methylated cap 1 structure on rhabdoviral mRNAs by their L proteins is thought to counteract IFIT1-mediated translational repression. However, IFIT1 was reported to inhibit VSV replication by sequestering 5'-ppp-ended viral RNAs in vitro and in vivo (Pichlmair et al., 2011). On contrary, IFIT2 rather than IFIT1 was shown to act as a restriction factor for replication of VSV specifically in neuronal cells of mice (Fensterl et al., 2012, 2014). Similarly, RABV replication is restricted by IFIT2 rather than IFIT1 in mouse brains (Davis et al., 2017). In addition, some mutations in the 2'-O-MTase motif (e.g., K1685A, K1829A) of the RABV L MTase domain are known to attenuate RABV in vitro and in vivo and cause its high sensitivity to IFIT2 (Tian et al., 2016). However, IFIT2 alone does not exhibit any activities to bind the 2'-O-unmethylated cap structures or 5'-ppp-ends of RNAs (Kumar et al., 2014; Fensterl et al., 2012),

although it can interact with AU-rich RNAs (Yang et al., 2012). Currently, the precise mechanisms of the antiviral actions of IFIT2 and IFIT1 against rhabdoviruses remain unclear.

RABV slowly intrudes the CNS with limited adaptive immune responses. RABV may have immunosuppressive strategies to escape from adaptive immune responses mediated by T and B cells in the CNS, although the underlying mechanisms remain largely elusive. In RABV-infected mice, expression of Fas ligand (FasL, CD95L) is induced in infected neurons, resulting in increased apoptosis of activated T cells expressing Fas (CD95 or Apo-1), which are transiently migrated to CNS tissues, via the Fas-FasL interaction (Baloul et al., 2004). Furthermore, infection of neurons with RABV causes up-regulation of PD-L1 (programmed cell death ligand 1, also called B7-H1) (Lafon et al., 2008), which is known to interact with PD-1 on T cells to repress T cell proliferation and cytokine production (reviewed in Chamoto et al., 2017). RABV infection also triggers neuronal expression of human leukocyte antigen (HLA)-G, a nonclassical immunosuppressive human major histocompatibility complex class I molecule, which binds its receptors on T and NK cells to prevent antiviral responses with these cells (Lafon et al., 2005).

Infection with laboratory adapted, attenuated RABV strains, such as vaccine strains, is known to efficiently induce production of virus-neutralizing antibodies against the G protein in infected hosts. Infection of mice with an attenuated RABV strain prior to secondary infection with a pathogenic strain promotes the clearance of the pathogenic strain from the CNS with neutralizing antibodies produced from B cells by enhancing the permeability of the blood-brain barrier (BBB) leading to the infiltration of immune cells into the CNS (Hooper et al., 2009). In contrast, infection with pathogenic strains does not change the permeability of the BBB in infected hosts, consistent with limited immune responses to these strains (Laothamatas et al., 2003, 2008; Roy et al., 2007; Hooper et al., 2009; Gnanadurai and Fu, 2016). Pathogenic RABV reduces inflammatory responses with the P gene products and, thereby, represses the elevation of the BBB permeability to counteract host CNS immunity (Long et al., 2020). Therefore, increasing the BBB permeability prior to intravenous administration of neutralizing antibodies may offer a new strategy for the future development of rabies treatment to enhance clearance of RABV from the CNS (Huang et al., 2014). Recently, simultaneous intracerebroventricular and intramuscular administration of neutralizing antibodies against the G protein was reported to increase survival rates of symptomatic mice infected with a pathogenic strain of RABV (de Melo et al., 2020), opening up a possibility to develop a new therapeutic intervention for the treatment of rabies.

Concluding remarks

Rabies is 100% preventable if post-exposure prophylaxis (PEP) with a vaccine and human immune globulin against RABV is administered immediately after exposure to RABV (Tantawichien and Rupprecht 2020). However, rabies still remains a persistent global public health threat especially in developing countries, where RABV is transmitted from wild animal reservoirs to unvaccinated domestic dogs followed by humans, but costly PEP is not always available. The World Health Organization set a goal to end human deaths from dog-mediated rabies by 2030 by increasing vaccination coverage in domestic dogs worldwide (Abela-Ridder et al., 2016). Although it is much more challenging to eliminate RABV from wild animals, oral rabies vaccines for wild animals, such as foxes, raccoons, coyotes, and skunks have been used to control RABV infection in wildlife and eventually to reduce the risk of infection of domestic animals and humans in some European countries and the United States (reviewed in Maki et al., 2017; Robardet et al., 2019). Currently, rabies elimination has been achieved only in a small number of countries, particularly island countries. Although there have been numerous studies on RABV in the past decades, the precise mechanisms of RABV spread, replication, immune evasion, and pathogenesis have not been fully understood. Further studies would certainly help in developing advanced strategies for the prevention, diagnosis, and treatment of rabies.

Acknowledgments

The author thanks Dr. Todd J. Green for providing the atomic coordinates of the model of the RABV L initiation complex that were used to generate the structural image for this chapter. The author's work described herein was supported by grants from the National Institutes of Health (AI093569 and AI146172).

Nomenclature

3CLpro	3C-like protease
ARDS	Acute respiratory distress syndrome
BAL	Bronchoalveolar lavage
C-terminus	Carboxy terminus
CDC	Centers for Disease Control and Prevention
CoV(s)	Coronavirus (es)
CTD	C-terminal domain
E	Envelope protein
EIA(s)	Enzyme immunoassay(s)
EM	Electron microscopy
ER	Endoplasmic reticulum
ERGIC	Endoplasmic reticulum Golgi intermediate compartment
GTIs	Gastrointestinal tract infections
hCoV(s)	Human coronavirus (es)
HCoV-229E	Human coronavirus 229E
HCoV-4408	Human coronavirus 4408
HCoV-HKU1	Human coronavirus HKU1
HCoV-NL63	Human coronavirus NL63
HCoV-OC43	Human coronavirus OC43
ICU(s)	Intensive care unit(s)
IFN(s)	Interferon(s)
kb	Kilobases
kDa	Kilodalton
LRTIs	Lower respiratory tract infections
M	Membrane protein
MERS	Middle East respiratory syndrome
MERS-CoV	Middle East respiratory syndrome coronavirus
N	Nucleocapsid protein

nsps	Non-structural proteins
NTD	N-terminal domain
N-terminus	Amino terminus
ORF	Open reading frame
PBM	PDZ-binding motif
pp1a	Replicase polyprotein 1a
pp1ab	Replicase polyprotein 1ab
RBD	Receptor-binding domain
RBM	Receptor-binding motif
RdRp	RNA-dependent RNA polymerase
RNA	Ribonucleic acid
RT-PCR	Reverse transcription polymerase chain reaction
RTC	Replication-transcription complex
S	Spike protein
SARS	Severe acute respiratory syndrome
SARS-CoV	Severe acute respiratory syndrome coronavirus
SARS-CoV-2	Severe acute respiratory syndrome coronavirus-2
sg	Subgenomic
TMDs	Transmembrane domains
URTIs	Upper respiratory tract infections
α	Alpha
β	Beta
γ	Gamma
δ	Delta

Properties of human coronaviruses

Coronaviruses (CoVs) are found worldwide and infect a variety of animals, causing illnesses that range from gastrointestinal tract infections (GTIs), encephalitis and demyelination; and can be fatal (Graham et al., 2013). Traditionally, the human CoVs (hCoVs) have been associated with mostly upper respiratory tract infections (URTIs) and GTIs in humans. In recent years, however, it has become increasingly evident that the hCoVs can cause more severe lower respiratory tract infections (LRTIs) such as bronchitis, pneumonia and even acute respiratory distress syndrome (ARDS) (van der Hoek, 2007), and can be lethal.

Classification

The CoVs belong to the family *Coronaviridae* in the order *Nidovirales*. The subfamily *Coronavirinae* can be further divided into four genera, viz. alpha (α)-, beta (β)-, gamma (γ)- and delta (δ)-CoVs (Table 1). Five of the hCoVs, i.e. HCoV-OC43, HCoV-HKU1, as well as the more pathogenic SARS-CoV, MERS-CoV and SARS-CoV-2, belong to the genus β-CoV. The remaining two hCoVs, HCoV-229E and HCoV-NL63, belong to the genus α-CoV (van Regenmortel et al., 2000; Prades et al., 2014).

Structure and genome

CoVs are spherical-shaped enveloped viruses with a diameter of roughly 100 nm (Davies and Macnaughton, 1979). The CoV particles contain a helical nucleocapsid that is formed by the viral genomic RNA and viral nucleocapsid (N) protein complex. Viewed under an electron microscope, the virus particle is surrounded by a “corona” or halo (Latin for “crown”) (Fig. 1A), from which its name derives (Coronaviruses, 1968). The halo is formed by the three major structural proteins spike, membrane, and envelope (S, M, and E) projecting as spikes from the viral envelope (Fig. 1B).

CoVs have positive sense, single-stranded RNA genomes ranging in size from 26 to 32 kilobases (kb), the largest of the known viral RNA genomes. Common to all CoVs, the genome is organized in the conserved order, 5'-replicase (1a/1b), spike, envelope, membrane and nucleocapsid-3' (Fig. 2). The genome has a 5'-cap and is 3'-polyadenylated (Pyrce et al., 2007). The 5' two-thirds of the CoV genome contain a large 5' frameshifted polyprotein (ORF1a/ORF1ab). The open reading frames (ORFs) produced by this polyprotein encode for proteins essential for viral RNA replication and are called non-structural proteins (nsps) (van der Hoek et al., 2006). The 3' one-third of the genome contain the genes encoding for the major structural proteins. Interspersed among, or even overlapping, these structural ORFs is a number of accessory genes. These subgroup-specific ORFs vary in number, location and size (Liu et al., 2014).

Table 1 Classification of the selected coronaviruses.

Genus	Species
α -CoV	Transmissible gastroenteritis coronavirus (TGEV)
	Canine coronavirus (CCoV)
	Porcine respiratory coronavirus (PRCoV)
	Feline coronavirus (FeCoV)
	Porcine epidemic diarrhea coronavirus (PEDV)
	Human coronavirus 229E (HCoV-229E)
β -CoV	Human coronavirus NL63 (HCoV-NL63)
	Bat coronavirus (BCoV)
	Porcine hemagglutinating encephalomyelitis virus (HEV)
	Murine hepatitis virus (MHV)
	Human coronavirus OC43 (HCoV-OC43)
	Human coronavirus HKU1 (HCoV-HKU1)
	Severe acute respiratory syndrome coronavirus (SARS-CoV)
γ -CoV	Middle East respiratory syndrome coronavirus (MERS-CoV)
	Severe acute respiratory syndrome coronavirus-2 (SARS-CoV-2)
	Avian infectious bronchitis virus (IBV)
δ -CoV	Turkey coronavirus (TCoV)
	Porcine Deltacoronavirus (PDV)

Genes and proteins

Spike protein (S)

S is a large protein (about 150 kDa) that trimerizes to form the distinctive spike structures on the surface of the virion. This protein facilitates viral entry into the host cell by mediating attachment of the virus to the host cell surface receptors. This is then followed by fusion between the viral and host cell membranes (Siu et al., 2008; Kirchdoerfer et al., 2016; Song et al., 2004). Attachment and fusion are facilitated by host proteases processing the S into S1- and S2-subunits (Millet and Whittaker, 2015). Next, the two subunits trimerize and fold into a metastable pre-fusion conformation. Research now shows that it's the S1-subunit that mediates receptor binding, while the S2-subunit is responsible for membrane fusion. The S1-subunit typically possesses two domains capable of binding to host cell receptors: an amino (N)-terminal domain (NTD) and a carboxy (C)-terminal domain (CTD) (Fig. 3) (Mou et al., 2013; Li et al., 2003).

For some CoVs, the expression of S at the cell membrane stimulates cell-to-cell fusion between infected and neighboring, uninfected cells. This formation of syncytia (i.e. giant, multinucleated cells) could possibly be a viral strategy that allows direct

Fig. 2 Schematic organization of human coronavirus (α and β CoVs) genomes. hCoVs contain large genomes about 26–32 kb in size. The 5'-end, two-thirds of the genome contain the overlapping open reading frames 1a and 1b. The remaining 3'-end one-third of the genome (expanded region) encodes for the structural spike (S), nucleocapsid (N), membrane (M), envelope (E), and accessory proteins (vary depending on the specific CoV).

spread of the virus between cells, thereby avoiding virus-neutralizing antibodies in the host serum (Glowacka et al., 2011; Qian et al., 2013).

Nucleocapsid protein (N)

The CoV N contains three conserved and highly distinct domains; two structural and independently folded structural regions, the NTD and a CTD, separated by an intrinsically disordered central region called the RNA-binding domain (Fig. 4). All three regions are capable of binding RNA, allowing N to bind the viral genome in a beads-on-a-string type conformation (McBride et al., 2014; Fehr and Perlman, 2015). N is a multifunctional protein and is abundantly produced within infected cells. Important functions of N include, binding to viral RNA to form the ribonucleocapsid and it has been proposed to play key roles in virus replication, transcription and translation. In host cells, N has been shown to target and interact with many host proteins, potentially leading to deregulation of the cell-cycle and inhibition of interferon (IFN) production, which probably plays a role in viral pathology (McBride et al., 2014).

Fig. 3 The S glycoprotein of the newly discovered SARS-CoV-2. Representation of the three-dimensional structure of coronavirus S. S1, receptor-binding subunit; S2, membrane fusion subunit; TA (or TM), transmembrane anchor; IT (or IC), intracellular tail. The one-dimensional structure of coronavirus S shows the NTD (N-terminal domain). FP (fusion protein or peptide), HR1 (heptad repeat 1), and HR2 (heptad repeat 2) are structural units in coronavirus S2 that function in-membrane. S1 and S2 are linked together by a polybasic amino acid bridge, which may be important in studying viral targeting (created with BioRender.com). Based on *An In-Depth Look Into the Structure of the SARS-CoV2 Spike Glycoprotein and Schematic of Spike-Receptor Binding Mechanism of SARS-CoV-2*, by BioRender.com (2020). Fig. 4 The coronavirus nucleocapsid (N). (A), (B) Domain organization of the SARS-CoV N protein with the intrinsically disordered regions (IDR), N terminal domain (NTD), linker region (LKR), and C-terminal domain (CTD) shown. In (A) the charged SR rich (striated box) and the nuclear localization signal (NLS, solid box) motifs are shown (McBride et al., 2014). (C) Phosphorylation (P, green) of the SR/RS dipeptides by cellular kinases prevents aggregation of N and leads to the assembly of soluble dimers with the acidic carboxyl-tail domains (N3) exposed (McBride et al., 2014; Nikolakaki and Giannakouros, 2020). (A) and (B) McBride R, Van Zyl M, and Fielding BC (2014). The coronavirus nucleocapsid is a multifunctional protein. *Viruses* 6: 2991–3018, (C) Nikolakaki E and Giannakouros T (2020). SR/RS motifs as critical determinants of coronavirus life cycle. *Frontiers in Molecular Biosciences* 7: 219. <https://doi.org/10.3389/fmolb.2020.00219>.

Fig. 5 The two predicted topologies of the coronavirus membrane (M). (A) In the first prediction, the M has three transmembrane domains (TMDs) located within the viral envelope. In this topology of the coronavirus M, the N-terminus domain (NTD) is found on the outside of the virion envelope and the C-terminus domain (CTD) on the inside of the virion. (B) In the second prediction, the M is presented with both the NTD and CTD at the outer surface of the virion. The TMDs are labeled 1–4.

Membrane protein (M)

M is the most abundant structural protein and defines the shape of the viral envelope (Neuman et al., 2011). This is a small (about 25–30 kDa) protein and contains three or four transmembrane domains (TMDs) (Fig. 5). Moreover, the protein has a small N-terminal glycosylated ectodomain and a larger C-terminal endodomain that extends into the virus particle (Fehr and Perlman, 2015). Homotypic interactions between the M proteins are the major driving force behind virion envelope formation but, on its own, is not sufficient for virion formation (de Haan et al., 2000). M needs to interact with all the major CoV structural proteins to drive the process of viral assembly (Masters, 2006). Critical for the incorporation of S into new virions, the interaction between S and M facilitates the retention of S in the endoplasmic reticulum (ER)-Golgi compartment (ERGIC)/Golgi complex where this incorporation can proceed (Mortola and Roy, 2004). M also interacts with N to stabilize the nucleocapsid (N-viral RNA complex), as well as the internal core of virions, thereby promoting completion of viral assembly (Narayanan et al., 2000). Together, M and E make up the viral envelope and their interaction is enough for the assembly and release of virus-like particles (Corse and Machamer, 2003).

Envelope protein (E)

E is a small protein (~8–12 kDa) present in low quantity within the viral structure. Interestingly, the sequence of CoV E proteins is not well conserved, but all have a common architecture (Fehr and Perlman, 2015). The E protein is a transmembrane protein, containing an N-terminal ectodomain and a C-terminal endodomain (Fig. 6). More recent studies have shown that the CoV E likely

Fig. 6 The primary structure of the coronavirus envelope (E). The primary amino acid sequence and predicted structural domains of the SARS-CoV E, which consists of the N-terminal domain (NTD), the transmembrane domain (TMD), and the C-terminal domain (CTD). The NTD is predicted to be on the external surface of the virion, with the CTD on the inside. The amino acid properties shown: hydrophobic (red), hydrophilic (blue), polar, charged (asterisks) (Schoeman and Fielding, 2019). Schoeman D and Fielding BC (2019). Coronavirus envelope protein: Current knowledge. *Virology Journal* 16: 69.

plays crucial roles in the viral replication cycle and immunopathology, including virion assembly, budding and release, apoptosis, inflammation and even autophagy (Schoeman and Fielding, 2019, 2020).

Accessory proteins

The accessory proteins are subgroup-specific ORFs that vary in number, location and size in the CoV genome (Liu et al., 2014). These ORFs share no similarity with accessory genes of CoVs belonging to other subgroups (Lai and Cavanagh, 1997), nor to any other known viral or cellular proteins. Even though CoV accessory proteins are believed to be mostly dispensable for growth in vitro (Oostra et al., 2007), these genes are maintained in the virus genomes under selective pressures. This is evidence that they likely confer some biological advantage to the virus in the natural environment, i.e. these proteins have a function in vivo in the natural host. These accessory proteins normally act by interfering with cellular processes, or by modulating virus-host interactions at the organism level. In fact, recent research proposes a wide range of possible functions for CoV accessory proteins, including modulation of viral pathogenicity and replication, acting as cell death inducers, and IFN antagonists, to name a few. Some of these accessory proteins have also been identified as minor viral structural components (McBride and Fielding, 2012; Oostra et al., 2007).

Viral replication

After binding to the cellular receptor, the CoV S undergoes conformational changes that lead to fusion between the viral envelope and the cell membrane (Fig. 7). The CoV then deposits its RNA genome into the host cytoplasm through endocytosis or direct membrane fusion. To synthesize viral subgenomic (sg) mRNAs, CoVs employ a discontinuous replication strategy (Pyrce et al., 2004). During the first stage of virus replication, the positive strand viral RNA serves as the mRNA for translation of two large proteins—ORF 1a and 1b—each encoding units of the RNA-dependent RNA polymerase (RdRp). The synthesis of the 1ab polyprotein involves a -1 ribosomal frameshift during translation of the 1a gene (Sawicki et al., 2007; Pyrc et al., 2004). The 1a and 1ab polyproteins (pp1a and pp1ab) are then cleaved by viral-encoded proteases to produce, on average 15–16, nsps. Typically, the 1a polyprotein is cleaved to form nsp 1–11, and the 1ab polyprotein gives rise to nsp 12–16. These nsps form the replicase-transcriptase proteins of CoVs and assemble, along with host and other viral proteins, into a membrane-bound replication-transcription complex (RTC). The active RNA polymerase transcribes full-length complementary (negative-sense) RNA, which is then copied into a positive sense sg mRNA. The subsequent transcription of the positive sense sg mRNA produces six distinct mRNAs, which includes the full length RNA genome, as well as a nested set of 3'-coterminal overlapping sg mRNAs. Each of the sgRNAs serves as a code for one of the ORFs downstream of the replicase gene. With the exception of ORF-E, the 5'-end of each ORF contains a transcription regulatory sequence of AACUAAA, which is essential for sg mRNA synthesis. Also, all the positive sense mRNAs share a leader sequence of approximately 70 nucleotides which is identical to the leader sequence of the genomic RNA. The viral membrane proteins insert into the ERGIC. As this happens, the full length viral RNA genome associates with the N. Next, the newly formed ribonucleoprotein complex interacts with the M in the ERGIC membrane and viral particles form as the nucleocapsid complex buds into the lumen of the ERGIC. The virus then moves through the ERGIC and exits the cell, most likely via exocytosis (Marra et al., 2003).

Pathogenic coronaviruses

Before 2003, only two CoVs, HCoV-OC43 and HCoV-229E (Tyrrell and Bynoe, 1965; Hamre and Procknow, 1966), were known to infect humans. In the years following the severe acute respiratory syndrome (SARS) outbreak, two additional HCoV were identified, viz. HCoV-NL63 (van der Hoek et al., 2004) and HKU1 (Woo et al., 2005). As far as we know, only HCoV-OC43, HCoV-229E, HCoV-NL63 and HKU1 continuously circulate in the global human population, resulting in infections throughout the year (Fielding, 2011). The first pathogenic CoV to cause severe acute respiratory tract disease in humans was identified in early 2003 (Drosten et al., 2003; Peiris et al., 2003b; Ksiazek et al., 2003). This novel CoV was eventually named severe acute respiratory syndrome CoV (SARS-CoV). In September 2012, the second pathogenic novel CoV was identified in two patients, of which one died

Fig. 7 Overview of the coronavirus (CoV) replicative cycle. After the CoV binds to its specific host cell receptor, the virus enters the cell by receptor-mediated endocytosis (1), and the genomic RNA is released into the cytosol (2); the latter is a result of the fusion of the endosomal and viral membranes. Next, translation of the viral genome yields the pp1a and pp1ab replicase polyproteins 1a and 1ab (pp1a and pp1ab) (3). Numerous internal proteases then cleave the polyproteins, and the resultant viral non-structural proteins (nsps) assemble into a replication-transcription complexes (RTCs) that engages in minus-strand RNA synthesis (4). During this step, both full-length and subgenomic (sg)-minus strand RNA are produced; the sg-minus strand RNA is then used as templates in the synthesis of the sg mRNAs which are needed to express the CoV structural and accessory protein genes (5,6). Ultimately, the (full-length) genomic RNA is encapsidated by multiple copies of the N protein and meets the structural proteins at the endoplasmic reticulum (ER)-Golgi intermediate compartment (ERGIC) and become enveloped by budding from smooth intracellular membranes (7,8). Finally, the new virions leave the cell by following the exocytic pathway (9) (de Wilde et al., 2018) (created with BioRender.com). Based on *SARS-CoV-2 Targeting of ACE2 Receptor and Entry in Infected Cell and Coronavirus Replication Cycle*, by BioRender.com (2020). Retrieved from <https://app.biorender.com/biorender-templates>.

(Zaki et al., 2012); this virus was eventually named Middle East respiratory syndrome CoV (MERS-CoV). Not until early 2020, was the third pathogenic hCoV—and only seventh CoV known to infect humans—identified and eventually named SARS-CoV-2 (Huang et al., 2020b).

Severe acute respiratory coronavirus (SARS-CoV)

SARS-CoV eventually spread to more than 30 countries, infecting ~8000 people with a mortality rate of ~10% (Fielding and Tan, 2007). The spread of the virus was eventually controlled by an unprecedented global health response and the virus has not been detected in the human population since April 2004.

Clinical features and pathogenesis

Even though SARS affects people of all ages, the majority of infections occur among adults with the median age 42–57 years. The elderly and individuals with a history of chronic comorbidities, including diabetes mellitus or chronic kidney failure, may have atypical presentations, such as lack of fever. Infections among children and adolescents, especially those younger than 12 years of age, are not common, and even if they do become infected, the disease is considerably less severe; the outcome is also much more favorable (Stockman et al., 2007).

The severity of SARS varies from asymptomatic infection to fatal acute ARDS, with asymptomatic or mild illness very uncommon. The initial, prodrome of symptoms of the disease are nonspecific and similar to a flu-like illness. One to two days after exposure to the virus, the patient develops early symptoms that could include fever, headache, chills, rigors, malaise, and myalgias (Pormohammad et al., 2020). Fever develops in all patients and is typically the first symptom, but it can also develop after the other initial symptoms. The lower respiratory tract phase of the illness follows after a further 3 or more days—but typically appears in week two—comprising of non-productive cough, shortness of breath and increasing respiratory distress sometimes requiring mechanical ventilation (Coleman and Frieman, 2014). Gastrointestinal symptoms, including diarrhea, vomiting and nausea have been recorded, but are not very common, with vomiting the least common; the diarrhea is often self-limiting. SARS-CoV has also been detected in other organs, including the kidneys, liver and spleen (Peiris et al., 2003a).

The most disturbing clinical feature of SARS is how fast many patients develop symptoms of acute ARDS. This is also the most common reason for admission to an intensive care unit (ICU). As soon as the second week after the onset of symptoms, pneumonia and hypoxemia linked to a rapid deterioration in the clinical condition of the patients may occur. Between 20% to 30% of patients admitted to hospital with SARS-CoV infection were admitted to an ICU, and about 75% of these patients required mechanical ventilation. Mechanical ventilation was required in approximately 16% of all SARS patients, and was associated with a mortality rate of about 50% (Fowler et al., 2003; Poutanen et al., 2003).

Epidemiology

SARS-CoV was originally believed to originate in civet cats, but these mammals were later shown to serve as intermediary hosts providing a source of infection to humans (Guan et al., 2003). Subsequent field epidemiological and molecular screening studies revealed that the most likely natural reservoir of SARS-CoV is horseshoe bats. Not only do many wild populations of horseshoe bats harbor several distinct SARS-like CoVs, many others have developed antibodies, indicating previous infection by the these CoVs (Lau et al., 2005; Wang and Eaton, 2007). Serological studies have now shown that SARS-CoV is a new human pathogen and had not previously circulated to any significant extent in humans prior to the outbreak in 2003 (Guan et al., 2003). The transmissibility of SARS-CoV between individuals is high and the virus appears to be transmitted primarily by large droplet spread and close contact. Transmission through fomites likely occurs as the virus remains viable for long periods on contaminated surfaces. Airborne spread, via droplets, is also likely to play a role in transmission between individuals (Low, 2004).

Middle East respiratory syndrome coronavirus (MERS-CoV)

MERS-CoV was the first pathogenic hCoV to be identified following the 2003 SARS-CoV outbreak. This CoV was originally isolated in June 2012 from a patient presenting with severe respiratory illness. Eleven days after admission to a hospital in Jeddah, Saudi Arabia, the patient—a 60-year-old man—died from renal and respiratory failure (Zaki et al., 2012). Since then, MERS-CoV infections were reported in more than 27 countries across the Middle East, Europe, North Africa and Asia, with the virus currently posing a potential threat in the Middle East where it is still sporadically detected in the human population (Chafekar and Fielding, 2018).

Clinical features and pathogenesis

MERS-CoV infections disproportionally affect adults, especially males, with children rarely affected (Arabi et al., 2014; Al-Tawfiq et al., 2016). Moreover, the virus typically causes more severe clinical manifestations in older people and, based on some evidence,

people with weakened immune systems. Those with chronic co-morbidities such as hypertension, obesity, diabetes, chronic lung disease, cardiovascular diseases or end-stage renal disease are also much more likely to be hospitalized when infected with MERS-CoV (Kim et al., 2017). In actuality, about 75% of MERS patients have at least one co-morbidity and MERS-associated fatalities are more likely to have other underlying medical conditions (Zumla et al., 2015).

Similar to SARS-CoV, MERS-CoV infection causes a clinical spectrum that ranges from asymptomatic (Drosten et al., 2014) to rapidly progressive, ARDS, septic shock and multi-organ failure, which can result in death (Al-Dorzi et al., 2016). In symptomatic individuals, the early symptoms are typically nonspecific, with patients reporting anything from general malaise, to a sore throat, low-grade fever, non-productive cough, chills, headache, shortness of breath and/or muscle pain. Less frequently, MERS-CoV patients present with gastrointestinal symptoms such as nausea, vomiting, anorexia, abdominal pain and diarrhea (Kapoor et al., 2014). Radiographs and computed tomography (CT) findings of the patient's chest are generally consistent with viral pneumonitis and ARDS (Zumla et al., 2015). Laboratory findings also include elevated lactate dehydrogenase levels, lymphopenia and thrombocytopenia (Arabi et al., 2014; Senga et al., 2017), with some cases resulting in elevated levels of creatinine, lactate dehydrogenase and liver enzymes (Zumla et al., 2015; Senga et al., 2017).

Patients who require hospitalization are typically admitted approximately 4 days after the onset of symptoms and the mean time spent in hospital is 41 days (Arabi et al., 2014). Worryingly, as much as 50% of adult symptomatic patients are admitted to ICUs, followed by between 40% and 70% then requiring mechanical ventilation within 7 days (Obobo et al., 2015). Reports indicate that between 22% and 70% of critically ill patients require renal replacement therapy (Arabi et al., 2014; Senga et al., 2017), but this needs to be confirmed since the higher end of this range could also be a result of hospital-acquired infections in patients with pre-existing kidney disease. In the end, MERS has a case mortality rate of about 36%, with the median time from the onset of symptoms to death about 11.5 days (Senga et al., 2017).

Epidemiology

Even though there is no conclusive evidence supporting bats as a source for transmission of MERS-CoV to humans, bats are hosts to MERS-CoV-like viruses (Corman et al., 2014). So, even though these viruses are genetically distinct from MERS-CoV, the possibility that bats serve as a primary animal host for MERS-CoV cannot be excluded (Memish et al., 2013). Importantly, the jump of MERS-CoV from bats directly to humans is currently purely speculative. There is some, although weak, evidence that the virus could have been transmitted to humans from dromedary camels (Reusken et al., 2013; Chan et al., 2015). This is primarily based on the presence of MERS-CoV-specific neutralizing antibodies specific in dromedary camels (Reusken et al., 2013), and one incidence of MERS-CoV infection in humans that could be linked to camels (Haagmans and Osterhaus, 2014). The transmissibility of MERS-CoV between individuals is low, and human-to-human transmission has only been observed in situations with prolonged close contact, such as health care settings, or in immunocompromised individuals with co-morbidities (Sharif-Yakan and Kanj, 2014).

Severe acute respiratory coronavirus-2 (SARS-CoV-2)

Clinical features and pathogenesis

The incubation period of COVID-19 is typically between 1 and 14 days, with most people showing signs of disease around a median time of 5–8 days. However, recent reports suggest that symptoms might even manifest up to 24 days after infection (Lauer et al., 2020; Bai et al., 2020; Guan et al., 2020). Following the incubation period, infected persons develop fever, dry cough, dyspnea, myalgia, and fatigue, features resembling pneumonia. Studies in China revealed that less common symptoms could include headache, diarrhea, hemoptysis, nausea, vomiting, sore throat, chest pain, chills, and a productive cough. ARDS is a feature seen in more severe cases (Chen et al., 2020a; Guan et al., 2020; Huang et al., 2020a; Wang et al., 2020b). Olfactory and taste disorders were also self-reported by patients from Italy (Giacomelli et al., 2020).

From a report in China, involving 72,314 cases, the majority of patients (~81%) only develop a mild form of pneumonia, or not at all; more severe pneumonia, characterized by shortness of breath, low oxygen saturation, and involvement of at least 50% of lung parenchyma in chest imaging, was seen in 14% of patients; and only 5% of patients became critically ill, developing shock or respiratory failure that required medical ventilation, or multi-organ dysfunction (Wu and McGoogan, 2020). Similar to SARS and MERS, the leucocyte count in majority of infected persons revealed lymphopenia, while the total white blood cell count may either be elevated or lower than normal. Additional biochemical factors such as procalcitonin, hepatic transamines, D-dimer, and prothrombin time were elevated in critical patients. The levels of plasma cytokines were reportedly higher in ICU patients than in non-ICU patients, suggesting that the cytokine storm is the basis for immunopathology (Huang et al., 2020a; Chen et al., 2020b; Yang et al., 2020). Almost all patients also exhibited abnormal chest radiographic features (Huang et al., 2020a). Chest X-rays frequently showed bilateral patchy shadows and ground-glass opacifications were seen in ARDS patients. Multiple ground-glass opacifications with or without reticular pattern, and parenchymal consolidations that involve both lungs were among the typical CT findings (Chung et al., 2020; Zhou et al., 2020b). It is worth noting that a report noted changes in CT scans from patients before the onset of clinical symptoms, even before viral RNA was detected in specimens from the upper respiratory tract (Shi et al., 2020). Recovery time varied depending on the extent of the infection; most patients recovering from mild infections were discharged after 2 weeks, whereas more severe cases recovered between 3 and 6 weeks, and approximately 2.3% of patients died from the infection

with a median time of 16 days after illness onset (Wu and McGoogan, 2020; Chen et al., 2020b; Wang et al., 2020b; Guan et al., 2020).

The pathogenesis of SARS-CoV-2 can range from merely manifesting as mild symptoms to more severe manifestations, such as respiratory failure. Pathogenesis begins after SARS-CoV-2 binds to epithelial cells in the respiratory tract and initiates replication, permitting migration of the virus deeper into the lungs to reach the alveolar epithelial cells. In the lungs SARS-CoV-2 replicates rapidly and can induce a strong immune response. This response is brought on by a cytokine storm syndrome, which culminates in ARDS and can be accompanied by respiratory failure. This is considered to be the main cause of death in patients with severe COVID-19 (Huang et al., 2020a; Mehta et al., 2020). Multiple organ failure, or dysfunction, is another serious sequelae reported in some cases of COVID-19 (Wu and McGoogan, 2020; Chen et al., 2020a; Yao et al., 2020). Although the exact nature of the SARS-CoV-2 pathophysiology is not yet clear, the immune system clearly plays an integral role as a combination of the cytokine storm and viral evasion of the cell-mediated immune response play very important roles in the progression and severity of the disease (Channappanavar and Perlman, 2017). Elevated levels of inflammatory cytokines and chemokines have been reported to result in lung injury and required patients to be urgently administered to the ICU (Huang et al., 2020a).

Given the target tissue of SARS-CoV-2, it stands to reason that the histopathological changes seen in patients with COVID-19 occur mainly in the lungs. Common histopathological features include bilateral diffused alveolar damage, formation of hyaline membranes, desquamation of pneumocytes, and in severe COVID-19 patients, fibrin deposits in the lungs. In some cases, exudative inflammation was also seen. Antigens of SARS-CoV-2 were detected in several tissue sites: the upper airway, submucosal gland epithelium, bronchiolar epithelium, as well as pneumocytes (type I and II), alveolar macrophages, and hyaline membranes in the lungs (Huang et al., 2020a; Chen et al., 2020a; Martinez et al., 2020; Zeng et al., 2020).

Epidemiology

The SARS-CoV-2 outbreak occurred in China and was traced to Huanan Wholesale Seafood Market, citing the market as the source of the outbreak (Ji et al., 2020). Based on the genetic evidence, SARS-CoV-2 was likely to have originated in animals, although when and where humans were first exposed to the virus is not known for certain. With some of the first reported cases having no epidemiological link to the Huanan seafood market, it is possible that the market may not have been the initial source of human exposure to SARS-CoV-2 (Li et al., 2020a). Horseshoe bats, however, are a particularly important source of both α - and β -CoVs (Zhou et al., 2020a; Fan et al., 2019; Li et al., 2005). The *Rhinolophus affinis* bat carries a CoV designated “RaTG13,” which is 96.2% identical to the full-length genome of SARS-CoV-2. All SARS-CoV-2 ORFs, including the hypervariable S protein and ORF8, are more than 90% similar to those of RaTG13 (Zhou et al., 2020a). More recently, *R. malayanus* was also reported to carry a CoV designated “RmYN02” which shares 93.3% of its genome with SARS-CoV-2. Both the clustering and the high genetic similarity between these bat CoVs and SARS-CoV-2 suggests that SARS-CoV-2 originated in bats (Paraskevis et al., 2020). The diverse number of bat CoVs found to be closely related to SARS-CoV-2 suggests that bats are the likely reservoir of SARS-CoV-2 (Lau et al., 2020).

Pangolins were initially the suspected source of the SARS-CoV-2 outbreak. Comparison of pangolin CoV genomes from the Guangxi and Guangdong provinces to the SARS-CoV-2 genome revealed that their sequences were 85.5% and 92.4% similar, respectively, to SARS-CoV-2 (Lam et al., 2020). The RBD of the Guangdong pangolin CoV is also highly similar to that of SARS-CoV-2, with only one variation in the RBM while still containing the five residues critical for ACE2 receptor binding (Xiao et al., 2020b). However, despite these similarities and having found SARS-CoV-2-related CoVs in pangolins, pangolins cannot be regarded as reservoirs for these CoVs (Xiao et al., 2020b; Lam et al., 2020). Bats, for one, can maintain a healthy physiological state while carrying CoVs. Pangolins infected with CoVs, however, exhibit clinical signs and histopathological changes indicative of CoV infection, suggesting that they are not natural hosts or reservoirs of SARS-CoV-2 (Xiao et al., 2020b).

Transmission

Although animals are the original source of the pathogenic hCoVs—transfer between the animal host or reservoir and humans after a spill-over event—global spread is driven by human-to-human transmission. The primary route of transmission for the pathogenic hCoVs is via the respiratory tract—i.e. pathogenic hCoVs are present in respiratory tract secretions, with tracheal secretions and bronchoalveolar lavage (BAL) specimens containing higher viral loads than nasopharyngeal swabs. Transmission typically occurs through close contact with an infected person, where infectious droplets and, in some cases, aerosols may come into contact with mucous membranes (Low, 2004; Deng and Peng, 2020). The spread by small droplet aerosols and droplet nuclei can also occur when much smaller and more numerous aerosol particles linger in the air and, when inhaled, can reach deep inside the lungs of a person; this has also been confirmed in recent studies for SARS-CoV-2 (Meselson, 2020; van Doremalen et al., 2020). This is thought to be a particularly important transmission route in enclosed rooms where large gatherings tend to take place (Stadnytskyi et al., 2020). Interestingly, the efficiency of transmission between individuals vary greatly between studies, and is likely associated with the degree of severity of illness and with the virulence of viral strains. Transmission through inanimate objects contaminated with infectious secretions occurs as CoVs remain viable for long periods on surfaces (Kampf et al., 2020), and has been a source of infection in healthcare settings (Bin et al., 2016; Gopalakrishna et al., 2004). These CoVs has also been detected in serum, feces and urine (Poissy et al., 2014). Increasing evidence also points to the possibility of, at least for SARS-CoV-2, transmission through contaminated feces. As an example, SARS-CoV-2 infected ferrets were found to have shed the virus in feces for up to 8 days after infection and is somewhat consistent with what was reported for some human studies (Wang et al., 2020d; Xiao et al., 2020a; Kim et al., 2020).

Laboratory diagnosis

Laboratory confirmation of pathogenic CoV infections has broadly included (i) molecular detection of CoV RNA; (ii) CoV antigen detection; or (iii) identification of a humoral response to previous infection (Mackay and Arden, 2015), often with varying degrees of success in terms of sensitivity and specificity.

During the SARS-CoV outbreak, a combination of serological and reverse transcription polymerase chain reaction (RT-PCR) assays was frequently used to confirm infection. Rapid diagnosis was most frequently made by RT-PCR using primers specific to the viral N-gene sequence. Throat, nasal, pharyngeal or serum samples were used to detect viral RNA by RT-PCR, as early as the first week of illness. During the second week of illness, stool and respiratory samples were also suitable for viral RNA assays. In rural areas, where expensive and complex molecular tests could not routinely be performed, enzyme immunoassays (EIAs) for viral N and S antigens were developed to screen suspected SARS cases (Bermingham et al., 2004; Chan et al., 2004). A positive real-time RT-PCR assay, targeting at least two different genomic regions of the MERS-CoV, can be used to confirm MERS. Probe and primer sets targeting the ORF1a and upstream of the E gene show the highest sensitivity and remain the most widely used for MERS-CoV confirmation assays (Corman et al., 2012). A single positive real-time RT-PCR test result, confirmed by gene sequencing, can also be considered positive for MERS-CoV infection (Chafekar and Fielding, 2018).

For a definitive COVID-19 diagnosis a combination of clinical manifestations, radiographical evaluations, and laboratory diagnosis, such as the detection of SARS-CoV-2 RNA (Zu et al., 2020), is required. SARS-CoV-2 viral RNA can be detected in a variety of samples, but it should be cautioned that not all samples are equally representative of the viral load, which could affect the diagnosis. Although SARS-CoV-2 can be detected in different parts along the respiratory tract, including from throat swabs, posterior oropharyngeal saliva, nasopharyngeal swabs, sputum, and bronchial fluid, samples from the lower respiratory tract contain a higher viral load since it is generally the target site of the virus (Zhou et al., 2020a; Pan et al., 2020; To et al., 2020b; Wang et al., 2020d; Han et al., 2020). Recommendations provided by the United States (US) Centers for Disease Control and Prevention (CDC) stipulate that BAL fluids, nasopharyngeal swabs (not throat swabs), and blood are all accepted clinical samples (CDC, 2020). However, when respiratory samples test negative, viral RNA can also be detected from the intestinal tract (Zhang et al., 2020). Since oral swabs commonly produce false positives, it is advised that multiple detection methods be used to confirm a COVID-19 diagnosis (Li, 2020; Xie et al., 2020). CT can be used in conjunction with laboratory testing to confirm a positive COVID-19 diagnosis. In Wuhan, when molecular detection services were overwhelmed, patients were screened for radiographic features of COVID-19. Features included bilateral multilobar ground-glass opacities along with peripheral or posterior distribution (Xie et al., 2020; Kanne, 2020). It is, therefore, recommended that patients who initially tested negative for viral RNA, but are strongly suspected of having COVID-19, receive chest CTs in conjunction with continued swab tests (Xie et al., 2020). Serological testing for the presence of pathogenic CoV-specific antibodies, such as those specific for the SARS-CoV-2 N or S protein, is another diagnostic method that proves useful for determining previous exposure to the virus. These tests can be used to quickly triage suspected cases of pathogenic CoV infection by confirming or ruling out infections *ex post facto*. It is, however, only useful in the later stages of the disease or even retrospective studies, after sufficient time has elapsed to mount an adaptive immune response (Zhang et al., 2020; Guo et al., 2020; To et al., 2020a). Of concern is that the extent and duration of the immune response can differ from patient to patient, and tests can vary in specificity and sensitivity (Bastos et al., 2020), possibly affecting the diagnosis. Nevertheless, good progress has been made regarding COVID-19 laboratory diagnostic methods, but the limitations warrant a combination of diagnostic methods to increase the reliability of a confirmed diagnosis. This, in turn, can help to accurately identify infected persons and consequently mitigate or limit the spread of SARS-CoV-2 (Lin et al., 2020).

Treatment and prevention

For the vast majority of pathogenic hCoV infections, supportive care, which includes rest, taking in fluids and analgesics are used, and mainly depends on the provision of organ support and management of complications. At times, broad-spectrum antibiotics, antivirals, IFNs and/or antifungals are prescribed to minimize the risk of co-infection with opportunistic pathogens (Momattin et al., 2013).

Ribavirin and corticosteroid treatment of SARS-CoV proved largely ineffective, since corticosteroids suppress the humoral and cellular components of the immune system (Feron et al., 2018). Other drugs, like pentoxifylline, were promising therapeutic candidates for treating SARS-CoV on account of its anti-inflammatory, antiviral, immunomodulatory, and bronchodilatory effects, but it proved largely unsuccessful in the clinical treatment of SARS-CoV infection (Bermejo Martin et al., 2003). Many antioxidant compounds demonstrate anti-SARS-CoV activity by inhibiting 3C-like protease (3CLpro), an enzyme vital to the replication of SARS-CoV (Jo et al., 2020). Accordingly, several studies of antioxidant compounds, including quercetin and quercetin-related compounds, reported the efficient inhibition of 3CLpro, in some cases reducing SARS-CoV replication (Ryu et al., 2010).

For MERS-CoV, monitoring epidemic patterns and investigating the spread of infection allows efficient identification, control, and prevention of possible pandemics. Combined treatment of MERS-CoV with ribavirin and IFN- α 2b was proposed as an early treatment since a combination of ribavirin and IFNs could inhibit MERS-CoV replication in vitro and improve clinical outcomes in MERS-CoV-infected non-human primates (Falzarano et al., 2013). The limited effective therapeutic window of MERS-CoV infections might also limit the efficacy of broad-spectrum antivirals when treating severe MERS-CoV patients (Widagdo et al., 2017). Alisporivir, a non-immunosuppressive cyclosporin A-analogue, inhibited MERS-CoV replication in vitro and could be

further potentiated by ribavirin, underpinning the potential use of cyclophilin inhibitors as host-directed, broad-spectrum inhibitors of CoV replication (de Wilde et al., 2017). However, since none of these potential anti-MERS-CoV candidates have demonstrated a significant benefit to treating acute MERS-CoV infections in a consistent and controlled manner, supportive management adapted from SARS-CoV guidelines has formed the basis for MERS-CoV treatment (Modjarrad, 2016). Various MERS-CoV vaccines have been designed, of which one has been progressed to clinical trials. Current MERS-CoV vaccines have been shown to induce effective protection in a few animal models (see review by Chafekar and Fielding, 2018).

Both researchers and pharmaceutical manufacturers are conducting large-scale clinical trials to evaluate a variety of COVID-19 treatment options. Some drugs, such as umifenovir (Arbidol), aim to block the binding of SARS-CoV-2 to the ACE2-receptor to prevent entry, but its efficacy is not yet established (Wang et al., 2020e; Zhu et al., 2020c; Li et al., 2020b; Lian et al., 2020). Camostat mesylate can also block the entry of SARS-CoV-2 into human lung cells (Hoffmann et al., 2020), but clinical data to support its efficacy is insufficient (Kawase et al., 2012; Zhou et al., 2015). Specific monoclonal antibodies (mAbs), recombinant human ACE2 receptors, or fusion inhibitors targeting the S protein have also been considered, but lack the required safety and efficacy parameters for clinical trials (Monteil et al., 2020; Tian et al., 2020; Xia et al., 2020b). SARS-CoV-2 viral replication inhibitors lopinavir and ritonavir (3CLpro inhibitors), and remdesivir, favilavir, and ribavirin (targets RdRp) have also been investigated (Wang et al., 2020c; Tahir ul Qamar et al., 2020; Williamson et al., 2020; Grein et al., 2020; Cai et al., 2020; Cao et al., 2020; Hung et al., 2020).

Immunomodulatory agents are used to mitigate the excessive inflammatory response induced by SARS-CoV-2. Dexamethasone reduced the mortality of COVID-19 hospitalized patients who received invasive mechanical ventilation by 1/3 and by 1/5 for patients who received oxygen support, but no benefit was found in patients who did not require oxygen support for COVID-19 treatment (RECOVERY, 2020; The Recovery Collaborative Group, 2020). Tocilizumab and sarilumab, antibodies (Abs) specific for the interleukin-6 receptor (IL-6R), were effective in treating severe COVID-19 by attenuating the cytokine storm (Xu et al., 2020). Preliminary results using eculizumab, a mAb which inhibits the proinflammatory complement protein C5, showed potential for treating severe COVID-19 cases by decreasing inflammatory markers and C-reactive protein (CRP) levels (Diurno et al., 2020). SARS-CoV-2 is reportedly more sensitive to type I IFN than SARS-CoV, making it a promising candidate in the early treatment of COVID-19 (Mantlo et al., 2020).

The Food and Drug Administration (FDA) approved convalescent plasma treatment as an adjunctive therapy for COVID-19 and preliminary results suggest that patients improved after treatment, but there are possible adverse effects (Duan et al., 2020; Shen et al., 2020). Conversely, mAbs can neutralize the SARS-CoV-2 infection both in vitro and in vivo and has an advantage over convalescent plasma therapy since it can be produced in much larger quantities to meet clinical demands (Wang et al., 2020a; Wu et al., 2020; Zost et al., 2020).

Several vaccines are currently being developed against SARS-CoV-2—recombinant vectors, DNA vaccines, mRNA in lipid nanoparticles, live-attenuated viruses, and protein subunit-based vaccines (Smith et al., 2020; Zhu et al., 2020b; Gao et al., 2020). Several of these are being tested in phase II trials and some have already advanced to phase III trials (Hu et al., 2020). An adenovirus type 5-vectored vaccine expressing the SARS-CoV-2 S protein produces a considerable humoral and cellular immune response in most recipients after a single immunization and has proven safe (Zhu et al., 2020a). An initial dose of the lipid nanoparticle-formulated mRNA vaccine candidate encoding the pre-fused SARS-CoV-2 S protein (mRNA-1273) induces a robust neutralizing antibody response in a dose-dependent manner, increasing after the second dose (Jackson et al., 2020). A whole virus, inactivated vaccine induces the production of neutralizing antibodies effectively and reported a low rate of adverse reactions (Xia et al., 2020a). These vaccine candidates show promise toward preventing and controlling the spread of SARS-CoV-2, but their safety and immunogenicity will need to be evaluated first with the aim of protecting healthy populations from the SARS-CoV-2 infection.

Until a successful, effective vaccine is produced and distributed, public health measures are the most effective at limiting the spread of SARS-CoV-2 and, to some extent, MERS-CoV. The ability of SARS-CoV-2 to remain viable on inanimate surfaces validates the need for proper sanitation through regular hand washing or the use of hand sanitisers with at least 70% ethanol. Despite some controversy over the efficacy of masks in reducing SARS-CoV-2 transmission, their mere presence acts as a physical barrier that can, in the least, minimize the spread of potentially virus-laden respiratory droplets from one person to another or onto surfaces.

Conclusions

Since the intermediary hosts for the pathogenic hCoVs have not been conclusively identified, there is always a likelihood that these CoVs could pose a problem, even after they are removed from the human population. Also, with no effective, ubiquitous therapeutic available for infections caused by the pathogenic hCoVs, the development of a vaccine remains a priority. Some of the challenges faced when developing a safe and effective CoV vaccine, include (1) host immunity to CoVs often wanes rapidly; (2) individuals requiring protection include the elderly and those with chronic co-morbidities; and (3) vaccines could instead of protect, worsen lung immunopathology (Enjuanes et al., 2008).

Taxonomy

The family *Parvoviridae* includes a large number of viruses infecting animals, sharing two main characteristics: (i) a linear, single-stranded DNA (ssDNA) genome, and (ii) a capsid formed by an icosahedral protein shell made of 60 protein subunits arranged in $T = 1$ symmetry, without envelope. Both genome and capsid have small dimensions, in the range 3.9–6.0 kb for ssDNA, and 20–28 nm for capsids, justifying the prefix name “Parvo-” (Cotmore et al., 2014).

Within the family, a major distinction is the separation in two subfamilies, the *Parvovirinae* infecting vertebrates, and the *Densovirinae* infecting invertebrate hosts. More recently, a third subfamily, *Hamaparvovirinae*, has been created to accommodate viruses of a possible ancient lineage, found to infect both vertebrates and invertebrate hosts (Penzes et al., 2020).

The criteria to assign a virus to the *Parvoviridae* family are mostly based on genome sequence information, obtained from culture-adapted isolates or directly from biological specimens. Genomes must conform to the general size and organization scheme characteristic of the family. The left side of the genome encodes for at least one large nonstructural (NS) protein, which must possess an SF3 helicase protein domain, while the right side contains the capsid protein (VP) coding region. Subdivision in genera and species is operated on the basis of sequence homology within the NS coding region, with a level of amino acid homology about 35–40% for viruses in the same genus, and >85% for viruses in the same species.

The current scheme approved by ICTV recognizes the three subfamilies, and further ten genera within the *Parvovirinae*, eight within the *Densovirinae*, and five within the *Hamaparvovirinae* (Table 1). Virus species in a same genus should be monophyletic. Species are identified with a binomial denomination, stating the main host taxon, the genus, and a progressive numeral. Within each species, different viruses and viral isolates can maintain their traditional name established in the literature. This classification scheme is regularly updated based on novel findings, brought also by the enormous potential for virus discovery of NGS technology and bioinformatic analysis, and in the future will probably undergo further refinement.

Table 1 Taxonomy of Parvoviridae.

Family	Parvoviridae		
Subfamily	Genus	No. of species	Type species
Parvovirinae	<i>Amdoparvovirus</i>	5	<i>Carnivore amdoparvovirus 1</i>

	<i>Penstylhamaparvovirus</i>	1	<i>Decapod penstylhamaparvovirus 1</i>

Taxonomic scheme within the family Parvoviridae, from ICTV [<https://talk.ictvonline.org/>]. In bold the genera or type species containing viruses known to infect humans.

General characteristics

Genome

A key feature of viruses in the family is a linear ssDNA genome, but it should be considered that the ssDNA is the form in which the genome is encapsidated, while it is converted in a double-stranded form (dsDNA) during its replication in cells. Depending on the different species, genomes of either polarity can be encapsidated at about the same frequency, or the negative polarity might be encapsidated at higher frequency. All members in the family present a similar organization of the genome, such that two terminal regions acting as replicative origins flank an internal region containing all reading frames and coding sequences for viral proteins.

The terminal regions can be inverted repeats (ITRs) or different between the two genomic ends, thus 'homotelomeric' or 'heterotelomeric', respectively. In both cases, they are composed of palindromic sequences around a site of dyad symmetry, allowing for fold back into a stem and loop configuration, a so-called 'terminal hairpin'. Mostly, the palindromes are imperfect, and can be present in two different arrangements, one the inverted complement of the other, usually referred to as 'flip-flop'. The hairpin structures are relevant for replication of the viral genome, providing priming for second-strand synthesis, and containing the cis-signals required to drive genome replication by a strand-displacement mechanism, according to a rolling hairpin model.

The internal region (IR) contains all open reading frames and the cis-signals that regulate the expression of the viral genome. Most viruses in the family have unisense genomes, such that ORFs are on a same strand (positive sense by definition), but viruses in the Densovirinae subfamily can show ambisense genomes, with ORFs distributed in the two strands. A common organization of the genomes is the division in two gene cassettes, the one (by convention, left side) coding for the non-structural protein(s) of the virus (NS), and the second (right side) coding for the virion structural proteins (VP). Within this common scheme, viruses differ in the actual number and distribution of coding sequences, and in the strategies adopted for the regulation of genome expression. At the transcriptional and post-transcriptional level, these include differences in the number and position of promoters, cleavage-polyadenylation signals, splicing signals, giving rise to an ample number of viral mRNAs on a genomic template of small dimensions. Further regulation can occur at the translational or post-translational level to expand the viral proteome or determine relative protein abundances.

In all viruses within the family, at least one major non-structural protein is produced (NS1), necessary for replication and regulation of expression of the genome, and a major player in the interaction with cellular proteome. Depending on the virus, a small set of other non-structural proteins can be produced, possessing accessory functions to replication, regulation of expression and interaction with the cellular environment. Concerning the structural VP proteins, at least two different proteins, and up to four, can be produced because of different mRNA processing, translational regulation or post-translational processing. All VP proteins are colinear and share common C-terminal sequences, differing mainly on the extension of the N-termini.

Structure

The capsid structure of many viruses in the family, at least one member per each genus, has been determined to atomic level, by studies exploiting X-ray crystallography and more recently cryo-electron microscopy (Mietzsch et al., 2019). The basic structure is a very simple icosahedral shell made of 60 VP proteins in a $T = 1$ arrangement. In all cases, a major VP protein, which is by norm the shorter form, provides ~90% of the capsid subunits, the remaining being contributed by the other longer forms. The common part of VP proteins provide the basic structure of the capsid shell. Each subunit consists of a core, formed by an eight-stranded antiparallel β -barrel motif, providing the capsid scaffold, while the amino acid insertions between the β -strands form long loops shaping the surface of the capsid. Typical is a cylinder at the 5-fold axis of symmetry, forming a channel to the interior, while the surface topology can alternate spikes, usually around the 3-fold axis, and depressions, around the 5-fold or at the 2-fold axis. Thus, the surface topology of viruses in the family can differ widely, with implications to the interaction with cellular receptors or immune system recognition.

The N-termini of VP proteins, especially those unique to the longer and less abundant forms, are not resolved in their topology because of intrinsic disorder and submolar abundance. These domains are normally buried within the capsid shell, but become exposed by extrusion through the 5-axis channel following interaction with cellular receptors or subsequent internalization steps. The N-termini of the smaller proteins are known to play essential functions in the viral lifecycle. In particular, they have a domain provided with enzymatic activity, a viral PLA2 phospholipase (vPLA2) which is essential for infectivity (Zadori et al., 2001), promoting endosomal escape following internalization.

Replicative cycle

The tropism of parvoviruses can be very selective, and results as a combination of receptor interaction and dependence on a permissive cellular environment (Mantyla et al., 2017; Ros et al., 2017; Qiu et al., 2017). Depending on the virus, a first interaction can occur with a glycan moiety on the surface of target cells, followed by a more specific recognition of a cellular receptor. Following attachment, internalization normally occurs via receptor-mediated endocytosis, in clathrin-coated vesicle or by other mechanisms depending on the virus. Externalization of the N-termini of minor capsid proteins with the enzymatic vPLA2 domain allows endosomal escape followed by nuclear localization. Final uncoating and extrusion of the viral genome occur in the nucleus, with the 3' end of the genome becoming accessible to cellular enzymes. This event may constitute the start of macromolecular synthesis, whose occurrence and outcomes are largely dependent on the interaction with the cellular replicative and transcriptional machinery.

The macromolecular synthesis at first involve the conversion of the incoming ssDNA in a dsDNA replicative intermediate, an event primed by the 3' end of terminal hairpins and operated by cellular enzymatic machinery. The dsDNA thus serves as a template for transcription to generate the set of mRNAs. Depending on the different viruses and genome organization, regulation of expression may depend on the use of different promoters, or on post-transcriptional processing of the pre-mRNA by a combination of regulated events. A biphasic pattern of expression can be recognized, with mRNAs encoding for non-structural and capsid proteins that may be produced in a sequential series of early and later events, the first leading to genome replication and the others to capsid proteins production and assembly.

Replication of the viral genome proceeds through intermediate dsDNA replicative forms (rfDNA). The terminal regions with their hairpin structure are the viral origin of replication, which are relevant for reinitiating DNA synthesis through site-specific recognition, single-strand DNA nicking and strand unwinding operated by the NS1 protein, in the so-called terminal resolution event. Primed by the 3' DNA end produced by the terminal resolution event, DNA synthesis proceeds through a continuous strand-displacement mechanism dubbed as 'rolling hairpin'. Thus, on a double-stranded template, novel single-stranded DNA molecules are produced, that can be converted to rfDNA to amplify the replication process, or finally packaged within preassembled capsid shells, before final maturation and egress of progeny virions from infected cells.

Virus-cell interaction and pathogenesis

Viruses in the family largely depend on functions provided by cellular environment for productive replication. Classically, parvoviruses have been divided as 'autonomous', capable of productive replication mainly exploiting S-phase cellular factors, or 'helper-dependent', typically the AAV, requiring coinfection with a helper virus to complete a productive replicative cycle (Weitzman and Linden, 2011; Meier et al., 2020). This distinction is blurred, since most viruses in the family are capable of modulating the cell cycle to their own advantage. The autonomous parvoviruses may establish long-term non-productive infections with long-term persistence of DNA in tissues, or their replication can be enhanced in normally non-permissive cells in the presence of a coinfecting helper. Dependent viruses on the other hand can undergo autonomous replication if the cellular environment becomes permissive in particular instances. The key characteristic of dependent viruses is their ability to integrate their genome into the host genome and establish true latent infections, which can be rescued by helper viruses with viral genome replication as autonomous genetic units. This property, coupled to advantage of absence of pathological effects, is successfully exploited by AAV-based transduction vectors (Li and Samulski, 2020).

Interaction with the cell environment is complex, and effects of infection, either productive or not, are multiple (Kailasan et al., 2015). Parvoviruses can interfere with the regulation of cell cycle, interact with the cellular DNA damage repair mechanisms, can induce apoptosis and trans-activate the expression of proinflammatory cytokines. Consequences can be a cytolytic effect on cells,

mostly by induction of apoptosis, or through induction of inflammation. Given the selective tropism of parvoviruses and the large dependence on actively replicating cells to achieve a productive infection, most infections are usually restricted to specific cell types or subpopulations, and the pathological effect on the host depend on the type and extent of virus-induced cell death. Association of parvoviruses with neoplastic conditions have been reported, but caution should be exerted in attributing a causal role and standby mechanisms are more likely. Because of the cytolytic effects, parvoviruses are regarded as oncolytic viruses and this property offers the opportunity to exploit these viruses for the development of oncolytic virotherapy (Angelova and Rommelaere, 2019; Bretscher and Marchini, 2019).

Human viruses

Viruses able to infect humans are found in the *Parvovirinae* subfamily, and are distributed in five out of ten genera. The adeno-associated viruses (AAV) in the *Dependoparvovirus* genus are considered non-pathogenic and are developed as safe and effective gene transfer vectors. Others belong to the *Erythroparvovirus*, *Bocaparvovirus*, *Tetraparvovirus* and *Protoparvovirus* genera. Among these, the most relevant human pathogenic virus is Parvovirus B19 (Qiu et al., 2017).

Parvovirus B19

Formally belonging to the species *Primate Erythroparvovirus 1*, Parvovirus B19 (B19V) was discovered in 1975 while screening blood donations against hepatitis B virus (Cossart et al., 1975). The virus was soon associated to a diverse group of clinical manifestations: acute anemic aplastic crises, mainly observed in the course of sickle cell disease (Pattison et al., 1981; Serjeant et al., 1981); chronic anemias in immunodeficient individuals (Kurtzman et al., 1987); the exanthematous fifth disease typical in children (Anderson et al., 1983, 1984); arthralgias observed mainly in adult patients with a tendency to chronicization (White et al., 1985; Reid et al., 1985); fetal hydrops or death when transmitted from pregnant women (Anand et al., 1987). Thereafter, the virus has been continuously implicated in an increasing number of diseases, involving to some extent and causal relevance a wide spectrum of different target organs and pathogenetic mechanisms.

Epidemiology and genotypes

B19V is widely circulating on a global scale, without any relevant geographical restriction. The virus is normally transmitted through the respiratory airway, favored by close family and community contacts. Circulation is seasonal, more prevalent in late spring/early summer, and can show local epidemic cycles every 4–5 years. Seroprevalence studies indicate that in general, about 50% of population can be infected within 25–30 years of age, reaching >90% in elder people (Mosson et al., 2008). Due to the spread of virus in bloodstream, there is a risk, although low, of transmission through blood, blood products or transplantation (Marano et al., 2015). The virus has the property of crossing the placental barrier, thus infection in pregnant women pose a risk of fetal infections with potentially severe consequences.

Three different genotypes are recognized for B19V (Servant et al., 2002; Gallinella et al., 2003a). The genotype 1 is the prototype and the main circulating genotype, prevalent in all geographic areas (Hubschen et al., 2009). Genotype 2 is considered an ancient genotype, mostly found as persistent genomes in tissue of elder people (Norja et al., 2006), or as DNA remnants from archived (Toppinen et al., 2015b) or even archeological specimens (Muhlemann et al., 2018), while is only sporadically found in patients as an actively circulating virus (Eis-Hubinger et al., 2014). Genotype 3 is the lesser circulating variant, more prevalent in geographic areas such as tropical Africa or Southern America, although with an expanding record (Hubschen et al., 2009). On a phylogenetic basis, the three genotypes possibly share a common ancestor, but presently form clearly separate clusters. The intertypic genetic distance is about 10%. Within each genotype, genetic diversity is lower for genotype 1, about 2–3%, and higher for genotypes 2 and 3, 5–8%. Further divisions in sub-genotypes (e.g., 1a, 1b, 3a, 3b) have been proposed, based on genetic distance and construction of phylogenetic trees (Parsyan et al., 2007). However, to our present knowledge, all genotypes share a same biological, immunological and pathogenetic profile (Ekman et al., 2007), and the main interest of reconstructing genome sequences is for molecular epidemiology evaluation.

Genome and structure

The genome is a 5.6 kb linear ssDNA molecule; either polarity is encapsidated at equal frequency (Zhi et al., 2004; Manaresi et al., 2017). The genome is homotelomeric, the terminal regions are constituted by inverted terminal repeats, 383 nts long whose distal 365 can form the hairpin structures. The internal unique region is 4830 nts long, and presents the typical organization with the two gene cassettes, for NS and VP proteins, at the left and right hand side respectively (Fig. 1). The hairpin terminal structures serve as origin of replication (Guan et al., 2009; Manaresi et al., 2017), and include cis-elements recognized by the viral NS1 protein (NSBE) (Tewary et al., 2014) and a binding site for the cellular STAT5 protein (Ganaie et al., 2017), all required for a functional replicative complex. A single promoter is located at the left end of the genome, at map position 6 (P₆), which requires cellular transcription factors such as Sp1 and Sp3 proteins, and is trans-activated by the viral NS1 protein (Raab et al., 2001, 2002). Other cis-elements

Fig. 1 B19V genome organization. Top: Major open reading frames identified in the positive strand; arrows indicate the coding sequences for the viral proteins. NS, non-structural protein; VP, structural proteins, colinear VP1 and VP2, assembled in a $T = 1$ icosahedral capsid (above); 7.5 kDa, 9.0 kDa, 11 kDa: minor non-structural proteins. Center: Schematic diagram of B19V genome. ITR, inverted terminal regions; IR, internal region; cis-acting functional sites: P₆, promoter; pAp1, pAp2, proximal cleavage-polyadenylation sites; pAd, distal cleavage-polyadenylation site; D1, D2, splice donor sites; A1.1, A1.2, A2.1, A2.2, splice acceptor sites. Bottom: Simplified transcription map of B19V genome, indicating the diverse mRNAs (mRNA 1–12) with introns (thin lines) and alternative splicing/cleavage forms (dashed), and their coding potential. have been mapped within the internal region, to promote pre-mRNA processing; in particular a pair of cleavage-polyadenylation signal in the middle of the genome (pAp1/2); a cleavage-polyadenylation signal at the distal (pAd) (Yoto et al., 2006); two different splicing donor sites, each with two possible acceptor sites; several regulatory elements such as intronic or exonic splice enhancers (Guan et al., 2011a,b). The combination in the use of these regulatory elements allows that on a genome of small dimensions, up to 12 mature mRNAs can be produced, with the potential to encode for a major NS1 protein, the two capsid proteins VP1 and VP2, and additional minor non-structural proteins, among which an 11 kDa protein has a demonstrated essential functional role (Zhi et al., 2006).

The icosahedral virion is constituted by VP1 and VP2 proteins, assembled in a ratio $\sim 1:10$. The C-terminal region common to both conforms to the general eight-stranded antiparallel β -barrel motif with intervening loops, providing the capsid shell and shaping the shell surface. The general appearance of the virion is rather smooth, prominent 3-fold axis spikes are absent, while smooth depression are present around the 5-fold and 2-fold axis (Kaufmann et al., 2004). The N-terminal portion of the VP1 protein, dubbed as VP1 unique region (VP1u), is possibly an exception to parvoviruses because it does not appear to be contained within the capsid, although it is not freely exposed in the mature virions (Kaufmann et al., 2008). Possibly, the VP1u region is maintained in a buried conformation proximal to the 5-fold axis, becoming fully exposed and accessible upon interaction of the capsid with the docking receptor, the neutral membrane glycolipid globoside (Bonsch et al., 2010). Typically, it has critical functions because of its associated vPLA2 enzymatic activity (Dorsch et al., 2002), and of a specific receptor-binding domain (RBD) at its extreme N-terminus (Leisi et al., 2013, 2016a).

Lifecycle

A striking property of B19V is its selective although not exclusive tropism for cells of the erythroid lineage in the bone marrow, in particular at their intermediate stage of differentiation. This selectivity is due to a double adaptation, the one due to binding of capsids to a cell-specific receptor with restricted distribution, the other linked to the requirement for replication of intracellular erythroid-specific factors, dependent on the erythropoietin pathway activation. Study of the biology of B19V has been favored by availability of primary cultures of erythroid progenitor cells, differentiated from peripheral blood and able to sustain B19V replication (Wong et al., 2008).

A first role in virus-cell interaction is due to globoside, a neutral membrane glycolipid that is also present on mature erythrocytes as antigen of blood group P (Brown et al., 1993). Docking of virions on globoside induces conformational modifications of the capsid shell, thus leading to extrusion of the VP1u region (Bonsch et al., 2010). This is followed by irreversible binding of its N-terminal domain to a specific binding partner on cells, which acts as the specific attachment receptor (Leisi et al., 2013, 2016a,b). The presence of globoside is necessary to achieve a productive infection, and individuals lacking globoside (a blood group antigen

polymorphism) are not susceptible to B19V (Brown et al., 1994), but it is not sufficient, and the internalization step depends on the role exerted by the VP1u region and the RBD (Quattrocchi et al., 2012; Bieri and Ros, 2019; Caliaro et al., 2019).

This process is highly specific and plays a key role in determining viral internalization within a specialized cell type. A wide distribution of globoside may support the capacity of B19V to bind other diverse cell types, but the VP1u receptor is present mainly on erythroid progenitor cells at the intermediate stage of differentiation (Leisi et al., 2015). This restricts infection to a very specific cell subpopulation characterized by a potentially permissive cellular environment apt to support viral replication. Other cell types, included endothelial or connective tissue cells, can be infected by mechanisms different from receptor-mediated endocytosis, mostly resulting non-permissive to viral replication. A relevant phenomenon observed for B19V is the antibody dependent enhancement of infectivity (ADE), that has been shown relevant for the infection of endothelial cells (through C1q receptor) (Von Kietzell et al., 2014), and for B lymphocytes from tonsil tissue (Pyoria et al., 2017).

As a further specific adaptation, the erythroid progenitor cells are permissive to viral replication only when stimulated by the lineage-specific growth factor erythropoietin (Chen et al., 2010a), while hypoxic conditions that are typical of the bone marrow milieu can enhance cell permissiveness to virus (Pillet et al., 2004; Chen et al., 2011). The signal transduction events triggered by Epo receptor activation promote binding of an activator protein, STAT5 in its phosphorylated form, to the viral DNA close to origin of replication, and this binding is necessary to replicate the genome in coordination with the activity of viral NS1 protein. Hypoxia converge on the same transduction pathways enhancing permissiveness to viral replication (Ganaie et al., 2017).

Initial phases of the replicative cycle follow the general scheme common to parvoviruses (Fig. 2). After surface docking and receptor recognition, they involve in sequence internalization by receptor-mediated endocytosis, escape from endosomal

Fig. 2 Outline of B19V replicative cycle in erythroid progenitor cells. 1: Virion binding to globoside, extrusion of VP1u region and binding to an erythroid specific receptor. 2: Clathrin-mediated endocytosis. 3: Virions in endosomal vesicles and vPLA2 mediated escape from endosomes. 4: Partial uncoating and externalization of viral ssDNA. 5: Translocation in the nucleus and complete uncoating. 6: Parental ssDNA and onset of macromolecular syntheses. 7: Hairpin-primed second strand synthesis. 8: Formation of a dsDNA replicative intermediate. 9: Early phase of transcription on the parental template, mainly yielding mRNAs for NS protein. 10: dsDNA terminal resolution by NS and priming of replication. 11: Replication by a rolling hairpin mechanism, via self-primed single-strand displacement mechanisms. 12: Late phase of transcription on the replicative intermediates, mainly yielding mRNAs for VP and 11 kDa proteins. 13: Progeny ssDNA released from the replicative intermediates. 14: Encapsidation of progeny ssDNA molecules in newly formed virions. 15: Accumulation of virions. 16: Release via cell lysis or apoptosis. degradation by vPLA2 activity, transport of nucleocapsids within the nucleus, and final uncoating of the genome in the nuclear environment. The initial phases of the replicative cycle are characterized by a low efficiency, and this can contribute to restriction of viral infectivity (Quattrocchi et al., 2012). Within the nucleus, macromolecular synthesis starts with second-strand synthesis primed by the 3' genomic end extruded from the capsid shell (Caliaro et al., 2019), also a step that can be restrictive to a productive replicative cycle (Gallinella et al., 2000). On the double-stranded template, transcription and replication can occur to achieve a productive replication (Bonvicini et al., 2006a, 2008).

For transcription, a single promoter is present at the left end of the genome, with a basal activity that is enhanced by the same viral NS1 protein in a positive feedback loop. Regulation of expression is obtained by the different usage of the cleavage-polyadenylation and splicing signals in the pre-mRNA, which can yield up to 12 different mature mRNAs, with differentiated coding potential. Expression of the genome is biphasic, with an early phase mainly producing the NS1 protein, followed after onset of genome replication by a late phase mainly producing the structural VP1 and VP2 proteins, and the 11 kDa as well (Bua et al., 2016). The switch in the expression profile is tightly linked to replication of the genome (Guan et al., 2008), which is exerted by the cell machinery redirected by the NS1 protein on the viral origin of replication, located within the terminal regions (Zou et al., 2018). Mechanistic details of replication conform to the rolling hairpin model, with the NS1 protein providing the endonuclease and helicase functions necessary for genome replication, unwinding and packaging into preassembled capsids (Luo and Qiu, 2015; Ganaie and Qiu, 2018).

Effects on cells

The effect of a productive replicative cycle in permissive cells, typically the erythroid progenitor cells, is mainly cytolytic due to the role of NS1 and 11 kDa proteins (Morita et al., 2001; Chen et al., 2010c). These contribute to dysregulation of the cell cycle, inducing a block in G2 phase, which is functional to the accumulation of cell factors needed for replication of the virus (Wan et al., 2010), and to induction of apoptosis by caspase cascade activation (Luo et al., 2013; Xu et al., 2017). A block in G1 induced by B19V has also been reported, due to the activity of NS1 protein and possibly by sensing of the incoming ssDNA and PRR activation (Morita et al., 2003). Intracellular sensing of virus and induction of an antiviral state, or induction of the innate immune response effector mechanism, are likely to occur but poorly investigated for B19V. The NS1 protein has trans-activating activity on several cellular genes including TNF α and IL-6, which may promote inflammation (Moffatt et al., 1996).

The tropism of B19V is not limited to erythroid progenitors. Other cell types can be infected by B19V, including endothelial cells (Duechting et al., 2008; Von Kietzell et al., 2014), connective tissue cells (Ferri et al., 2002; Zakrzewska et al., 2005), and synovia (Ray et al., 2001; Mehraein et al., 2003). In these cells, infection is normally non-productive but the interaction with virus can induce dysregulation of cell physiology and/or trigger inflammatory processes (Duechting et al., 2008; Ray et al., 2001). Uptake of virus in these cells may not follow the same pathway as in erythroid progenitors, and can be favored by immune complex recognition (Von Kietzell et al., 2014). The cell environment is normally non-permissive, and following internalization the viral genome may be degraded, or maintained within cells in a silenced state, or be able to express only early genes without replication. Expression of early genes might not lead to replication of the genome, but the NS1 protein can induce alterations to the cell environment, including apoptosis, inflammation and necrosis, or induction of cell physiology dysfunction. The VP1u region with its associated vPLA2 activity may contribute to the development of an inflammatory process and cell dysfunction. In these cell types, only sporadically the virus has been shown able to complete a productive replication with production of viral capsid proteins (Adamson-Small et al., 2014).

A peculiarity of B19V is its tendency to persistence in tissues following acute infection (Bua and Gallinella, 2017). When sought by molecular methods, viral DNA can be detected although at low levels in 25–50% samples from tissues as disparate as bone marrow, lymphoid organs, liver, kidney, joint and bones, skin, thyroid, testis (Manning et al., 2007). Endothelia and connective tissue cells are very likely a diffuse reservoir for persistence (Norja et al., 2006), and B-lymphocytes in tonsils have been shown to harbor virus (Pyoria et al., 2017). Association is long-term, possibly lifelong, providing a permanent record of the infection and being a marker for molecular epidemiology. Discrimination of a persistent active infection, with possibly a low expression of viral genes and pathological consequences, from the mere presence of silenced DNA is a difficult task, but is crucial to distinguish conditions of clinical relevance. Reactivation of persistent, silenced viral genome has been hypothesized, but systematic evidence is lacking and a general assumption should be avoided.

Infection and pathogenesis

Initial studies on B19V pathogenesis involved experimental infection of volunteers (Anderson et al., 1985; Potter et al., 1987). B19V is normally transmitted through the respiratory airway. Whereas a primary site of replication has not been identified, tonsils can be a possible portal of entry. Then, the virus gains access to the bloodstream and following a primary viremic phase that is clinically unapparent, reaches its primary target organ constituted by the bone marrow. Within the bone marrow, the virus can infect erythroid progenitor cells, achieving a productive infection and exerting cytotoxic effects. The cytolytic effects exerted mainly at the proerythroblast stage of differentiation can induce a block in the erythropoiesis process. In this phase, the bone marrow can show erythroid aplasia and the presence of characteristic giant erythroblasts, which are considered typical of B19V infection (Koduri, 1998). The effects on bone marrow are derived from cell-cycle arrest, block of erythroid differentiation and eventually apoptosis of susceptible and infected cells on one side, and from the dimension and turnover rate of the erythroid compartment on the other.

The fact that the more undifferentiated precursors are resistant to infection ensures that the block in erythropoiesis is temporary, and can be relieved by the development of a neutralizing immune response (Young and Brown, 2004).

A balance is reached between cell population dynamics and viral replication, depending on the dynamics of erythropoietic compartments and the immune response (Brown, 2000; Kerr, 2015). At the peripheral level, reticulocytes can be low or absent, while erythrocytes and hemoglobin level are only marginally decreased because of the long lifespan of mature red cells. Anemia becomes evident and can be severe if there are concurrent defects in the erythropoiesis process, expanding the erythroid compartment or limiting the lifespan of erythrocytes, or immune system reactivity, with delayed viral clearance. Thus, from the hematological side, the possible clinical manifestations depend on the combination of infection and the physiological and immune status of the individuals (Fig. 3).

In a normal individual, with physiological erythropoiesis and normal immune response, infection is limited in extent and temporal frame, usually asymptomatic from the hematological point of view, and is controlled by the development of neutralizing antibodies. The productive infection supported by bone marrow leads to a secondary viremia that in the initial phase, before the development of an effective immune response, can reach exceedingly high viremic levels (10^{12} virus/mL). Clearance of infection, determined by detection of virus in the blood, takes usually 3–4 months with constantly decreasing levels, while sustained persistence of viral DNA in peripheral blood implicates active chronic infection (Musiani et al., 1995; Lindblom et al., 2005; Lefrere et al., 2005). Very low levels of DNA can be detected for years in peripheral blood, with the caveat of discriminating virus from circulating DNA (Molenaar-De Backer et al., 2016).

Infection becomes manifest as acute or chronic pure red-cell aplasia (PRCA) with peripheral anemia when defects in the erythropoiesis process or in the immune response alter the balance between viral replication and cellular turnover (Young and Brown, 2004). In case of stressed and expanded erythropoietic compartment, because of a reduced lifespan of erythrocytes or increased need, such as observed in hemoglobinopathies, typically sickle cell disease, or thalassemia, or other cellular or enzymatic deficits, infection by B19V can lead to an acute episode of profound anemia, that presents as the classical aplastic crisis in patients with underlying hematological disorders. This acute phase is normally relieved by the development of a specific immune response. On the opposite, when the immune system has not the capability to control, neutralize and clear viral infection, infection can become persistent and lead to chronic anemia. This last situation does not require underlying deficits in the erythropoiesis, and can occur in case of congenital or acquired immunodeficiency, in cases of concurrent malignancies, in the course of chemotherapy, or immunosuppressive treatments, such as in bone marrow or solid organ transplant recipients.

The secondary viremia leads to the systemic distribution of the virus and involvement of secondary target organs, by direct or indirect pathogenetic mechanisms. Thus, in this second phase, infection may become clinically apparent with diverse manifestations, some common, some rarer. Among the commonest, B19V is responsible of the erythema infectiosum (fifth disease), typical of children, and arthritis, typical of adults. Involvement of the skin normally takes the clinical feature of an erythematous rash with typical distribution, from cheeks to trunk and limbs, and appearance. Typical in childhood, it can also be present in adults, and its appearance may be more varied with respect to the classical picture and include necrotic or vasculitic lesions. Arthritis is mainly but

Fig. 3 Course of B19B infection in normal individuals. Viremia is determined by qPCR in peripheral blood, while class-specific antibody response (IgG, IgM) can be determined by EIA and expressed as index value (ratio sample to cut-off). Values are indicative but representative of a normal course of infection in otherwise healthy individuals. Resolution of infection, clearance of viremia, persistence of IgM and IgG have a variable outcome, with a delayed course (dashed lines). In case of ineffective immune response, the infection can assume a chronic course with virus persistence, different levels of detectable antibodies, and possible persistent clinical manifestations.

not exclusively observed in adulthood and is more subject to chronicization. In this case, macrophage-like synovial cells appear to be involved in a local inflammatory infiltrate, with tendency to regress without long-term sequelae.

The range of clinical manifestations associated to B19V infection has been constantly increasing, to involve almost all organs and tissues and including systemic syndromes, and descriptions of clinical presentations have progressively stressed atypical aspects (Table 2). Categories broadly include: (i) hematological disorders other than those involving the erythroid series, rare and in some case severe, often on an immunopathological basis; (ii) organ specific involvement (myocarditis, hepatitis, encephalitis, glomerulonephritis, etc.) on a sporadic basis; (iii) association to systemic disease, possibly by triggering autoimmune mechanisms; (iv) infection in the immunodeficient patient; (v) association to malignancies (e.g., pediatric leukemia/lymphoma, thyroid cancers). The sporadic nature of these associations makes problematic both a definite assessment of a causal relationship, and the individuation of pathogenetic mechanisms, and calls for accurate diagnostic evaluation.

In the systemic phase of infection, endothelial cells may play a relevant role. Endothelia constitute a diffuse tissue that can account for the wide distribution of virus in disparate organs. Endothelial cells can be infected by B19V and, normally non-permissive, can be a site of persistence of the viral genome (Zakrzewska et al., 2005). In the systemic phase, the pathogenic process may depend upon direct cytotoxic or pro-apoptotic effects or via stimulation of an inflammatory response by viral proteins, such as the NS protein or the VP1u vPLA2 (Duechting et al., 2008). The interplay with the immune systems, by its innate and adaptive recognition mechanisms, may lead to the development of immunopathological mechanisms, for example linked to immune complex deposition, or to the onset of autoimmune processes. These may contribute to local effects, for example in the development of glomerulopathies (Chandra and Kopp, 2013), or present as systemic, linked to connective tissue diseases or with features reminiscent of systemic lupus (Lunardi et al., 2008; Kerr, 2016).

In recent years, B19V has been detected at increasing frequencies in endomyocardial tissues. B19V has been directly involved as an etiologic agent in sporadic acute myocarditis both in pediatric and adult populations (Bock et al., 2010; Molina et al., 2013). Active B19V infection has been shown in myocardial endothelial cells, so B19V probably acts by inducing endothelial dysfunction, which in turn triggers inflammatory responses in the cardiac tissue (Kuhl et al., 2003; Bultmann et al., 2003). The definition of a possible role of B19V in the development of chronic cardiomyopathies and cardiac dysfunction is instead matter of ongoing debate (Verdonshot et al., 2016; Rigopoulos et al., 2019). The frequency of B19V DNA detected in cardiac bioptic samples is constantly

		Congenital anemia
		Neurodevelopmental delay (?)

A compilation of diseases and clinical manifestations associated to parvovirus infection. Frequent clinical manifestations are typical of B19 infection, although the presentation and course of disease can vary depending on the physiological and immune status of the individuals. Sporadic clinical manifestation include diseases that have been more rarely associated to B19 infection, occurring at a low frequency and without any predictable concurrent factor. The list of sporadic clinical associations is not exhaustive. (?) denotes uncertain association.

high, and a marked cardiotropism should be mentioned as one of the main characteristics of B19V. A positive association and a role of B19V in the development of inflammatory chronic cardiomyopathies has been proposed because of significant higher mean viral loads or the presence of viral mRNAs, suggesting active viral replication and expression.

The role of B19V in transplantation has been investigated for solid organ and bone marrow transplant recipients (Eid et al., 2019). In solid organ, a higher relevance has been found for kidney transplants (Ki et al., 2005; Barzon et al., 2009) while for bone marrow it is a sporadic but clinically relevant event (Broliden, 2001; Plentz et al., 2004). Other immunodeficient patients at higher risk are pediatric leukemia patients (Kerr and Matthey, 2015), where B19V infection affects to a significant level on the clinical course and response to treatments (Lindblom et al., 2008). The possibility that chronic B19V infections may act as a trigger in preneoplastic situations has been hypothesized but needs sounder evidence (Vasconcelos et al., 2011). A possible link to oncogenic processes has also been proposed for thyroid malignancies (Hobbs and Adamson-Small, 2015).

A relevant property of B19V is its ability to cross the placental barrier and infect the fetus. Placental trophoblasts are not permissive to the virus but may consent access of virus to the fetal circulation (Jordan and Deloia, 1999; Jordan and Butchko, 2002; Wegner and Jordan, 2004). Endothelial placental cells can be productively infected (Pasquinelli et al., 2009), facilitating the establishment of fetal infection and contributing to placental damage. In the fetus, the virus can infect erythroid progenitor cells, in liver and/or bone marrow depending on the gestational age, and exert direct cytolytic effects (Morey et al., 1992a). The ensuing block in fetal erythropoiesis can be severe, because of the physiologically expanded erythropoietic compartment combined to an immature immune response, and lead to profound fetal anemia, fetal hydrops and/or fetal death. The immune status of the mother plays a protective role, and intrauterine infections are confined to primary infections in non-immune pregnant women. The rate of transmission, 30–50%, will depend on the gestational age, being higher in the first two trimesters, while the effect on the fetus, ~10% severe effects, will depend on its developmental stage, the rate of expansion of its erythroid compartment and maturity of fetal immune response. Infections occurring at earlier stages carry a higher risk of leading to fetal deaths, while the development of hydrops is more frequent in the central part of pregnancy. Hydrops may lead to fetal death, or the fetus may more frequently recover without persistent damage. In the third trimester, the overall risk of fetal damage decreases so that fetal death is a rare event (Bascietto et al., 2018; Xiong et al., 2019; Bonvicini et al., 2017b). The virus is not teratogen, and only sporadic B19V-related fetal complications are described in documented intrauterine infections. Long-term neurological effects in congenitally infected children are reported and attributed to the grade of fetal anemia rather than to a direct effect of virus (Lindenburg et al., 2013).

Immune recognition

The pattern of innate immune recognition is not known to detail, although general symptoms related to cytokine production are typical of a prodromal phase of infection (Isa et al., 2007; Wu et al., 2016). In case of primary infection, IgM are produced first and are detectable starting a few days after the viremic peak, then decreasing and lasting for about 3–6 months. IgG follow soon and are generally detectable lifelong. Due to a slow viral clearance, viral DNA can still be detected for months or longer periods even in the presence of specific IgG, as it can happen in the case of chronic infections with production of non-neutralizing antibodies (Young and Brown, 2004).

Antibody reactivity is directed mainly against the viral capsid shell and can be neutralizing. Epitope mapping on B19V virions is incomplete. The capsid shell is known to present conformational epitopes, and an atomic structure of Fab binding to capsid has been resolved (Sun et al., 2019). Additional linear epitopes have been mapped, many on the VP1–2 common region (Sato et al., 1991; Yoshimoto et al., 1991), others and most relevant for neutralization of infectivity being located on the VP1u region (Saikawa et al., 1993; Anderson et al., 1995), and especially in the extreme N-terminus, coincident with the RBD (Zuffi et al., 2001).

IgM mainly recognize conformational epitopes in the VP1–2 common region (Manaresi et al., 2001). IgG also recognize conformational epitopes in the common region, and in addition they can be directed against linear epitopes mainly in the VP1u region (Manaresi et al., 1999; Musiani et al., 2000). A maturation of the immune response includes recognition of an acute-phase epitope on VP common region (Kaikkonen et al., 1999, 2001), then an expansion of the repertoire by progressive selection of high-avidity clones producing antibodies recognizing VP1–2 conformational epitopes and VP1u linear epitopes (Soderlund et al., 1995a,b). Antibodies against NS1 protein can also be detected in about 30–40% of seropositive individuals, without any significant association to duration, severity or presentation of disease (Venturoli et al., 1998; Heegaard et al., 2002). Cell-mediated immunity is less characterized. B cell reactivity (Tolfvenstam et al., 2000), T cell CD4 and CD8 reactive clones can be detected (Tolfvenstam et al., 2001; Isa et al., 2005), but very few antigenic determinants have been identified so far (Kasprowicz et al., 2006a,b).

Immune deficits favor persistence of active, chronic infections (Isa et al., 2006). Deficits range from the inability to produce detectable antibodies, to the production of a transient immature response, with low-level IgM without the switch to IgG, to the production of IgG that are inefficient in neutralizing the virus, as unable to recognize mature phase neutralizing epitopes. Except in cases of profound deficits, a chronic infection usually evolves and lastly an immune response is mounted, able to control infection, although the course of events can be prolonged and unpredictable.

Diagnosis

A laboratory diagnosis is required to confirm or exclude a clinical suspect, can be included as part of larger diagnostic panel, or be carried out for screening purposes (Gallinella, 2018). The mainstay is detection of a specific antibody response in serum/plasma from peripheral blood, with coupled detection of IgM and IgG. Automated or semi-automated methods make use of EIA/CLIA

assays, using as antigens the capsid proteins, produced as recombinant proteins in heterologous expression systems. VP proteins are able to self-assemble in viral-like particles (VLPs), composed of VP2 only or VP2 + VP1 antigens (Brown et al., 1990; Kajigaya et al., 1991); or VP2 plus VP1u segment produced as isolated fragment (Soderlund et al., 1992). Depending on the assay used a diverse set of epitopes are recognized, but use of VP2 only can be sufficient to obtain correct discrimination of reactive samples (Manaresi et al., 2004). Line blot assays are also available to better dissect the antibody repertoire against a combination of conformational and linear epitopes, also including the NS1 protein (Kerr et al., 1999). More recently, singleplex and multiplex microsphere-based Suspension Immune Assays (SIAs) are being developed (Wang et al., 2016). An intrinsic limit of immunological diagnosis is due to the evenience of an acute phase infection before the development of antibodies (virus positive, antibodies negative), or of a chronic infection with or without presence of IgG (virus positive, antibodies either positive or negative). The presence of IgM is suggestive of acute infection, but false reactivity linked to polyclonal activation or technical issues should be considered. The presence of IgG without IgM is normally considered as a sign of past infection and immunity, but chronic infections can go undetected if virus is not sought.

The use of molecular assays to detect viral DNA is the necessary complement to immunological diagnosis to discriminate active infections in case of relevant clinical suspect, and if the subject has known immune deficiencies (Gallinella et al., 2003b). Molecular detection should also be recommended for screening, for example in pregnancy, or as pre- or post-transplantation protocols. The presence of viral DNA in peripheral blood is a marker of active infection, but due to the long-term persistence and slow clearance following the initial phase of infection, a quantitative assay is necessary to determine viral load as an essential parameter in evaluation of the clinical course. Standardized qPCR assays have been developed to this purpose, with the additional requirement of equal detection of all genotypes (Gallinella et al., 2004; Bonvicini et al., 2013; Toppinen et al., 2015a). Detection of virus in tissues, including bone marrow or fetal samples, can be carried out by qPCR, but in situ hybridization and/or immunocytochemistry may better serve as assays discriminating active infections from mere persistence (Morey et al., 1992b; Bonvicini et al., 2006b).

Prevention and treatment

To prevent iatrogenic transmission by blood or blood products, screening by molecular assay has been introduced, in particular as a voluntary standard adopted by manufacturing companies (Marano et al., 2015). A threshold of 10^4 IU/mL (IU are NIBSC International Units (Baylis et al., 2012)) has been proposed for limit of acceptable contamination without risk of transmission to susceptible individuals. For protection in the general population, or at least at-risk subjects, a vaccine would be useful. In fact, a vaccine against B19V is technically feasible by use of VLPs, but after a long history it is still under development and not in any priority line for introduction on a general basis (Bansal et al., 1993; Ballou et al., 2003; Bernstein et al., 2011; Chandramouli et al., 2013; Penkert et al., 2017).

Concerning treatment, the infection in most case provokes mild and self-limiting diseases, but in serious cases, supportive or symptomatic treatment is required. Transfusions are necessary to support anemic patients in acute aplastic crisis or in case of chronic infections. Intrauterine transfusions can be carried out to improve favorable outcome of infected and anemic fetuses, justifying antenatal screening and non-invasive follow-up for B19V in pregnancies (Oepkes and Adama Van Scheltema, 2007; Lindenburg et al., 2014). The only treatment currently used for B19V are IVIG, which normally contain high levels of antibodies (Onodera et al., 2018) and can be used for replacement treatment in case of immune deficiencies and chronic infections (Crabol et al., 2013). Anti-inflammatory drugs are used in cases of arthralgias, although relief may not be effective. None of these treatment options is specific to B19V, and resolution of infection will eventually depend on the ability of the immune system to control and clear infection.

Development of specific antiviral strategies should be considered a major topic in research on B19V (Manaresi and Gallinella, 2019). Antiviral compounds that showed efficacy in *in vitro* assays include hydroxyurea and Cidofovir/Brincidofovir. Hydroxyurea is an antiproliferative drug used in the treatment of sickle-cell disease that also showed inhibitory activity against B19V (Bonvicini et al., 2017a). Its use in SCD pediatric patients correlates with milder clinical presentation of B19-induced aplastic crisis (Hankins et al., 2016), but whether this effect might be due to the antiviral activity is not determined. The nucleotide analogs Cidofovir and its lipid conjugate Brincidofovir are broad-range antivirals active against dsDNA viruses, which showed an antiviral activity also against B19V (Bonvicini et al., 2015, 2016; Bua et al., 2019). Unfortunately, their use is limited by severe toxic side effects, and systematic clinical evaluation of their efficacy against B19 has not been carried out yet. Continuing effort in the field is required to find specific, effective and safe treatments for B19V infection.

Human Bocaviruses

Bocaviruses are a large group of viruses found in several vertebrate hosts. Human Bocavirus was first discovered in 2005 (Allander et al., 2005) by unbiased direct molecular investigation in respiratory secretions. Identification of the first species, HBoV1, was then followed by HBoV2–4 (Kapoor et al., 2010) found in feces. Bocaviruses are able to infect the respiratory or intestinal mucosa, with a limited propensity to systemic spread and tissue persistence. They are recognized human pathogens, causing respiratory and gastrointestinal infections, although their relevance as such is blurred by their wide distribution, mainly subclinical course or association to mild diseases, and by the presence of other viruses coinfecting a same tissue in more severe cases.

Epidemiology

There are four Human Bocaviruses species, HBoV1–4, which are similar but not identical in biology and capacity to cause diseases (Jartti et al., 2012). HBoV1 is mainly a respiratory virus, while HBoV2–4 are mainly found as associated to gastrointestinal infections. Circulation is widespread and, by seroprevalence, most infections occur in the first years of life. HBoV1 is the more diffuse species in the population, transmitted through the respiratory route and reaching a prevalence of 80% by 6 years of age. HBoV2–4 are not found in respiratory secretions, but can be found in stool samples, indicating a fecal-oral transmission. Seroprevalence is about 50% at the age of six for HBoV2, 20% for HBoV3 and very low for HBoV4. Molecular epidemiology suggests a wide circulation of viruses but fails to indicate any association with different biological or clinical features.

Genome and structure

All Bocavirus species share a similar genetic organization and structural features, but most studies have been carried out for HBoV1 (Huang et al., 2012). The genome is ~5.5 kb linear ssDNA molecule; 95% of encapsidated genomes are of negative sense polarity (Fig. 4). The terminal regions are heterotelomeric, constituted by an imperfect palindromic hairpin of 140 nt at the left-end and a perfect palindromic hairpin of 190 nt at the right-end, both being required for replication of the genome. The internal unique region is ~5200 nts long, encoding on the left hand side a group of non-structural proteins, NS1–4, a viral nucleoprotein, NP1, in the middle of the genome, and the colinear viral capsid proteins, VP1–3, on the right hand. A single promoter is located at the left end of the genome, at map position 5 (P_5). *cis*-elements mapped within the internal region to promote pre-mRNA processing include two cleavage-polyadenylation signal in the middle (pAp) and at the distal end of the genome (pAd), and four different splicing donor/acceptor sites. The three VP proteins originate from a same mRNA by different regulation of translation initiation. The icosahedral virion is constituted by VP1, VP2 and VP3 in a ratio ~1:1:10; as for other viruses in the family, the common region constitutes the shell, while the N-terminal VP1 unique region (VP1u) includes a domain with vPLA2 enzymatic activity.

Lifecycle

Bocaviruses infect terminally differentiated epithelial cells in the airway (HBoV1) and intestinal (HBoV2–4) mucosae. The replicative cycle has been studied in detail in polarized airway epithelial cell cultures for HBoV1 (Deng et al., 2013), which can

be infected and release virus for long periods, establishing a model of persistent productive infection that may correlate with what happens in vivo. In these cell cultures, the virus can infect cells by the apical and basolateral surfaces, while it is released mainly by the apical surface.

The virus does not require actively dividing cells to achieve a productive replication. In fact, replication is cell cycle independent and the virus recruits the cellular DNA damage repair machinery to replicate the genome, including cellular DNA repair DNA polymerases, in viral DNA replication centers (Chen et al., 2010b; Luo et al., 2011; Deng et al., 2017). For replication of the genome, both a rolling hairpin and a rolling circle mechanism have been proposed (Schildgen et al., 2012). Transcription of the viral genome occurs starting from a single promoter, and by use of different cleavage-polyadenylation and splicing signals, gives rise to at least 12 mature mRNAs translated in non-structural proteins NS1–4, the nucleoprotein NP1 and the three viral capsid proteins VP1–3 (Zou et al., 2019).

Pathogenesis and infection

In cell cultures, HBoV1 infection induces damage of the epithelial layer and airway tract injury, including disruption of the tight-junction barrier, loss of cilia, and epithelial cell hypertrophy. Infection is at last cytolytic, but airway epithelium is regenerated by basal stem cells, which can maintain integrity and sustain prolonged virus release. Infection also upregulates release of cytokines, which may contribute to disease.

As human pathogenic viruses, a distinction can be made between HBoV1, which is mainly a respiratory virus, and HBoV2–4, which are mainly gastrointestinal viruses (Moesker et al., 2015; Christensen et al., 2019). HBoV1 can be detected in nasopharyngeal secretions by molecular detection techniques, in a large proportions of cases of upper and lower respiratory tract infections, from 2% to 20%, thus indicating a pathogenic potential. However, in a large part of cases, up to 80%, HBoV1 is not the only virus detected, being found in association to one or more other potential pathogenic agents. A high viral load or other marker of active virus replication is suggestive of a more direct role of HBoV1, but its tendency to give long-term persistent infections explains its frequent detection and questions its pathogenetic relevance (Martin et al., 2015). Thus, HBoV1 may cause upper or lower respiratory tract infections, which may have different degrees of clinical relevance, while in its detection in association with other viruses may be due to a standby phenomenon, favored by a same route of transmission and the tendency of HBoV to persist for prolonged times in infected tissues. Alternatively, a coinfection may be more clinically relevant because of concurrent pathogenetic activity. Similarly, HBoV2–4 have a wide circulation but their pathogenic potential is even more unclear (Paloniemi et al., 2014). They have been associated to pediatric gastroenteritis, but also in this case they are often been detected with other viral pathogens, especially rotavirus and norovirus. Infection has mild clinical consequences, if any, and coinfection does not exacerbate clinical conditions. As it happens for Parvovirus B19, also for HBoV there are increasing reports on atypical clinical presentations or involvement in other diseases that require further confirmatory studies.

Immunity

The capsid shell constitutes the main target for a specific immune response, with production of antibodies with neutralizing activity (Kantola et al., 2011). The four different viruses share a structure similarity of about 80–90% in the major VP3 protein. The presence of a common antigenic repertoire, explains for an extended immune cross-reactivity, which can be a confounding factor when using serology as a diagnostic tool. Moreover, the phenomenon of ‘original antigenic sin’ seems to take place, as an anamnestic cross-reactive activation upon infection with different HBoV types (Li et al., 2015). A strong cellular immunity is induced, and a CD4 specific response has been characterized for HBoV1 (Lindner et al., 2008), with a sustained release of cytokines in blood and secretions (Chung et al., 2008; Hirose et al., 2014).

Diagnosis

For a diagnosis of clinical relevance, a combination of molecular and antibody detection is advisable. Detection of viral DNA by qPCR is the method of choice for detection of virus in nasopharyngeal secretions or stools, and assays able to distinguish and quantitate the different HBoV types is required (Kantola et al., 2010). A high viral load can be suggestive of acute infection and causal association with clinical manifestations, while a lower load can be more indicative of a delayed viral clearance. Detection of specific antibodies is possible by using VLPs as antigens in EIA/CLIA assays (Kantola et al., 2008). In addition to prevalence studies, utility of antibody detection is important. Seroconversion, increase in IgG titer or IgM detection is strongly suggestive of a recent infection, and can be a valid support to discriminate clinically relevant episodes (Hedman et al., 2010). The cross-reactivity between HBoV species require a cautious approach to interpreting results and possibly the introduction of technical steps to discriminate a species-specific response (Kantola et al., 2011; Li et al., 2015).

Treatment

No specific treatment is available, and its need can be questionable as long as a clear pathogenetic role is established.

Human Tetraparvovirus

The so-called Human Parvovirus 4, now *Primate Tetraparvovirus 1*, was discovered in 2005 in the serum of a HBV infected person with acute febrile disease. Now, three different genotypes are known (Matthews et al., 2017). The virus has not been adapted to cell culture and information on its genome sequence is incomplete, so knowledge about its biology and lifecycle is limited. The internal coding region is known for its full length, so its transcription map and coding potential, which include at least two non-structural proteins (NS1–2) and two capsid proteins (VP1–2) forming the capsid shell.

The virus, with its three genotypes, can sporadically be detected in blood, but the clinical relevance is unclear. Its frequent association with viruses such as HIV, HBV, HCV, and in subjects such as injected drug users, suggest a parenteral route of transmission. In most cases, infection as determined by high viremic loads appears asymptomatic, and does not alter the clinical course of underlying infections. Symptomatic infections manifest as a febrile illness are rare and mainly linked to immunodeficient states. Diagnostic is rarely performed and it relies on quantitative molecular detection techniques, while detection of specific antibodies by EIA assays is possible by the availability of recombinant VLP. Seroprevalence studies indicate a diverse prevalence in the general population, not exceeding 40% in sub-Saharan Africa and close to zero in northern countries.

Human Protoparvoviruses

More recently, novel parvoviruses have been found in human stool samples (Vaisanen et al., 2017). Such viruses have not been isolated, but relevant genome sequence information recovered from clinical specimens allowed the definition of new viral species and their inclusion in the Protoparvovirus genus. Among these viruses, the Human Bufavirus (BuV), with three different genotypes, has been detected more frequently and an association with gastroenteritis has been proposed. The Human Cutavirus (CuV), also detected in stool samples, has been detected in skin tissue, and appears highly associated to cutaneous T-cell lymphoma. Seroprevalence studies indicate a wide circulation of BuV with a differential geographical distribution, higher in African and middle/central-east countries, lower for European countries and United States, while circulation of CuV is more limited. Discovery of these new viruses poses interesting challenges to the characterization of biology and definition of clinical relevance (Soderlund-Venermo, 2019).

Introduction

The *Arenaviridae* family was established in 1976 predominantly harboring rodent-associated viruses, made up of the single genus *Arenavirus* with species distributed in different regions around the world. After the discovery of different arenaviruses in *Alethinophidian* snakes, the family taxonomy was substantially modified and amended including the reptilian viruses in the genus *Reptarenavirus* and renaming the original *Arenavirus* genus as *Mammarenavirus* (Radoshitzky et al., 2015). A new genus *Hartmanivirus* was later added which owes its name to the Haartman Institute snake virus (HISV) isolated from a boa constrictor in captivity. Finally, in 2018 the last genus *Anntenavirus* was included, made up of the Wénling frogfish arenaviruses 1 and 2 (WIFAV-1/2), found in toad fish, and at the International Committee on Taxonomy of Viruses Report Consortium 2019 the taxonomy was restructured including the family in the Bunyavirales order (Abudurexiti et al., 2019).

The family includes more than 40 species, some reptarenaviruses cause boid inclusion body disease in captive snakes (Hetzel et al., 2013), whereas some mammarenaviruses can infect humans and other primates, causing severe and sometimes fatal diseases. Mammarenaviruses have been divided into two groups based on antigenic properties and geographical location: Old World (OW) or Lassa-lymphocytic choriomeningitis serocomplex include viruses indigenous to Africa, Asia and the worldwide ubiquitous lymphocytic choriomeningitis virus (LCMV), whereas New World (NW) or Tacaribe serocomplex include viruses from the Americas (Wulff et al., 1978; Charrel et al., 2008). NW arenaviruses are further subdivided into four clades named A, B, C, and A/Rec (Clade D), on basis of the nucleoprotein (NP) sequences. Clade A/Rec (Clade D) is hypothesized to be a recombination of clades A and B that includes North American viruses such as Whitewater Arroyo virus (WWAV), Bear Canyon virus (BCNV) and Tamiami virus (TAMV) (Radoshitzky et al., 2015).

Virions are spherical or pleomorphic particles, ranging from 50–300 nm in diameter, composed of helical nucleocapsids within a dense lipid envelope. A variable number of cellular ribosomes, which are not required for virus multiplication, are also found inside the particle and the family name originated from this peculiar granular structure (arenosus, from the Latin arena) observed in electron-microscopic thin sections (Rowe et al., 1970). *Arenaviridae* was traditionally thought to be a family of bi-segmented RNA viruses with two single-stranded RNA molecules called L (large, 7.1 kb average) and S (small, 3.4 kb average), both with an ambisense coding strategy. This is true for mammarenaviruses, but there is genome diversity in other genera, such as the antennarenavirus genome comprising three segments termed small, medium and large (Shi et al., 2018). Each RNA fragment is closely associated to the L protein, the viral RNA dependent RNA polymerase, and covered by the NP, forming the nucleocapsid or ribonucleoprotein (RNP) in the interior of the virion. The external envelope has a lipid membrane where the viral spikes or glycoprotein (GP) complex are inserted forming tetramers, composed of three proteins that arise from proteolytic cleavage of the

precursor GPC by the cellular subtilase S1P/SKI: the surface exposed GP1 protein, the transmembrane GP2 protein and the stable signal peptide SSP, that is unusually retained in the mature GP complex. Immediately below the membrane and closely associated with it, it is located the matrix protein Z, a small protein with an important RING-finger motif able to bind zinc that is highly conserved. The structural proteins in fish and reptile arenaviruses may exhibit some differences in comparison to the structure of mammarenaviruses above described, particularly about the presence in the virion of Z or SSP.

Given their importance as human pathogens, the focus of this article is on OW and NW mammarenaviruses, the more characterized members of the family.

Pathogenic arenaviruses

Epidemiology

The *Mammarenavirus* genus contains the highest number of viruses that cause hemorrhagic fever (HF) in humans, most of them located in Clade B of the NW group. However, the most important pathogen is Lassa virus (LASV), a member of the OW that causes approximately 100,000–300,000 annual infections and about 5000 deaths, primarily in West Africa (McCormick et al., 1987). Infections with arenaviruses in South America are seasonal and significantly lower, with 100–1000 cases reported per year but with higher mortality rates of 15–35%, in the absence of treatment. Junin virus (JUNV) is the most recognizable pathogen among this NW group and is the causative agent of Argentine HF (AHF). Machupo (MACV), Guanarito (GTOV), and Sabiá (SBAV) viruses are the causative agents of Bolivian HF, Venezuelan HF, and Brazilian HF, respectively. Other arenaviruses pathogenic to humans have emerged more recently. These include Chapare virus (CHAPV) in Bolivia, and Lujo virus (LUJV) in Southern Africa (Delgado et al., 2008; Paweska et al., 2009). Additionally, another NW arenavirus, WWAV, was implicated in human disease in North America (Fulhorst et al., 1996).

With more than 40 members, the weight of the genus *Mammarenavirus* accounts by including many important, deadly-human pathogens. Some of them such as LASV, JUNV and MACV have been reported to recurrently produce severe disease whereas others have appeared with rare (CHAPV), small clustered (LUJV, WWA) or unique occurrence (SBAV). Here we will focus on those that pose biggest threat to human populations either by the severity of the disease or the size of the population affected. Fig. 1 geographically locates OW and NW arenaviruses, highlighting the pathogenic members and its animal reservoir.

OW human pathogens

Lassa fever (LF), caused by LASV, is mainly endemic to the West African countries of Guinea, Liberia, Nigeria, and Sierra Leone (Owolabi et al., 2016). About 80% of people who become infected with LASV are asymptomatic or have mild symptoms. This is supported by the moderate to high seroprevalence of LASV specific antibodies in endemic regions, along with an annual rate of up to 20% for LASV specific seroconversion within nonimmune populations (McCormick et al., 1987; Lukashevich et al., 1993; Tomori et al., 1988). Therefore, newer estimates claim LASV more likely affects 2–3 million people annually (Richmond and Baglole, 2003).

LF can affect all age groups and both genders (Akpede et al., 2018). From those who develop severe disease and get hospitalized fatality rate raises up to 10%. Pregnant women, children under 5 years of age, and individuals infected with human immunodeficiency virus or other immunosuppressive conditions have an increased risk of death. Pediatric LF is known to occur more commonly in male children for as yet unknown reasons. The mortality rate can be as high as 87% among women infected with LASV during the third trimester of pregnancy (Price et al., 1988) and vertical transmission has proved to occur. Also, prolonged detectable Lassa viral RNA in blood and semen suggests the possibility of sexual transmission (Raabe et al., 2017).

Fig. 1 Geographical distribution of OW and NW mammarenaviruses. The location for each arenavirus and the year of isolation is indicated. For HF-causing viruses, designated in bold, the animal reservoir is shown.

Fifty years after its discovery in 1969 in Nigeria, LF outbreaks have continued in West Africa with an enlarged number of cases in 2016, 2018 and 2019 outbreaks (Ilori et al., 2019; Iseri et al., 2018; Owolabi et al., 2016). LASV is now on the World Health Organization Blueprint list of priority pathogens for which there is an urgent need for accelerated research and development.

The genus prototype species LCMV produces subclinical, often mild human infections with a mortality rate lower than 1%, and the recovery from even severe disease occurs without sequelae in most cases. Approximately 5% of humans show evidence of previous infection with LCMV (Jamieson et al., 2006; Peters, 2006). On the other hand, given that LCMV is a neurotropic virus, congenital infection can produce a spectrum of pathologic effects from minimal to severe, depending on the developmental stage of the fetus at the time of infection (Bonthius et al., 2007). In some cases, infection may result in abortion (Jamieson et al., 2006) and the mortality rate of infants diagnosed with congenital LCMV is approximately 35% (Wright et al., 1997). Moreover, LCMV infection has been reported in immunocompromised patients, often proved to be fatal.

NW human pathogens

JUNV causes AHF in agricultural lands and at an increasingly large area of the country. The seasonal distribution of the illness and the prevalence in male rural workers reveals the risk of occupational exposure to humans and the habits of the host-rodents. Annual incidence within the endemic area may be as low as 1 in 100,000 but in the areas of highest activity it reaches 140 per 100,000 population and 355 per 100,000 adult males. Most infections with JUNV result in mild clinical disease (Enríe et al., 2008; Weissenbacher et al., 1987). About 70–80% of infected humans will self-resolve with no consequences while the remaining 20–30% will develop hemorrhagic or/and neurological manifestations. When untreated, the case fatality for AHF is 10–30%, which is lowered to 1% when treated with serum from patients who have recovered (Enríe et al., 2008). AHF is the only arenavirus related condition for which both efficient therapy and vaccination have been stabilized. These topics will be addressed on the corresponding sections.

Bolivian HF (BHF) was first described in human patients in the Beni district of Northeast Bolivia near the city of San Joaquin during an outbreak which lasted from 1959 to 1963. BHF, as other South American arenavirus HF, resembles AHF symptomatology, with a total mortality rate of around 25% (Webb, 1965). With the reemergence of BHF in 2006, an increase in the number of cases has been reported annually with a peak in 2008 (Aguilar et al., 2009). Patterson et al. (2014) extensively reviewed the knowledge on this disease highlighting that there has been minimal research for the development of countermeasures or treatment for BHF. Although more studies have been done on the biology of MACV, limited in-field information is available. Lack of accessible material or data from clinical new samples, the difficulty and remoteness of the region, and the geopolitical environment within Bolivia, makes this disease overlooked.

Reservoirs and transmission

The main groups at risk of infection by arenaviruses are laboratory workers who perform virus purification procedures, people in contact with rodents in endemic areas, and healthcare providers working with infected patients. In areas where these viruses are present, field workers are particularly at risk because of their close contact with infectious rodent excrete.

As zoonotic agents capable of transmitting diseases from animal to human, mammarenavirus circulation follows its natural host reservoir distribution. With exception of the nonpathogenic Tacaribe virus (TCRV) that circulates in bats, all identified mammarenaviruses have rodent species as natural reservoirs (Childs and Peters, 1993; Salazar-Bravo et al., 2002). Of note, TCRV was recently isolated from *Amblyomma americanum* ticks in Florida (United States), opening the possibility of viral evolution through adaptation to arthropod hosts (Sayler et al., 2014).

OW members, other than the prototype LCMV, are associated with reservoir rodents of the genus *Praomys*, instead NW viruses associate with rodents from the subfamilies *Murinae* and *Neotominae*. LCMV, which reservoir corresponds to the urban worldwide-spread mouse *Mus musculus*, is the only member found globally. All other members of the genus are geographically restricted, due to the wild to rural features of the rodents acting as reservoirs. Then, the incidence rate of the human disease produced by arenaviruses is highest when local population densities of the reservoir increases, rising the human to rodent contact likelihood. Arenaviruses cause acute or persistent infections in rodents without any major life-threatening associated symptoms. Infected animals show chronic viremia and spreading of the virus through urine, saliva, and feces to other rodents, and accidentally to humans (Childs and Peters, 1993; Martínez Peralta et al., 1979). Thus, it is assumed that humans become primarily infected with arenaviruses through material contaminated with excretions or in aerosolized droplets of secretions from infected rodents.

Human vertical transmission from the infected mother to her fetus during pregnancy is not rare for LCMV and LASV (Barton et al., 2002). LCMV transmission through solid organ transplantation from infected donors has been also documented (Fischer et al., 2006; MacNeil et al., 2012). Person-to-person transmissions are infrequent and restricted to LASV, MACV and SBAV. These cases have been particularly well documented in LASV endemic region by intra-family or nosocomial exposure, via contact with body fluids of ill persons or the use of contaminated instruments in medical procedures (Fisher-Hoch et al., 1995; Kernéis et al., 2009). Human infection with LCMV may also occur from pet hamsters and serious infections acquired by laboratory workers were also reported. Despite all before mentioned and because person-to-person spread has occurred in very specific settings, like hospitals or research laboratories, interpersonal transmissibility is considered more an exception than a primary route of infection.

In addition to the high human risk of contagion in endemic regions, the increase in international air travel has contributed to the transport of LASV to other geographic areas such as Europe, the United States, and Japan. (Amorosa et al., 2010; Choi et al., 2018; Ehlikes et al., 2017) Importantly, in January 2020, AHF was diagnosed in a woman in Brussels (Belgium) who had traveled from

Argentina to Europe (Veliziotis et al., 2020). This case demonstrates also the real risk of imported NW HF outside South America, as another unexpected infectious agent with threatening features. Finally, arenaviruses also have the potential to be used as agents of bioterrorism outside of their endemic regions.

The arenavirus multiplication cycle

Entry

Virus entry into the host cell is mediated by the envelope glycoprotein complex that conform the trimeric spike: the receptor binding protein GP1, the transmembrane fusion protein GP2 and the small SSP. Arenavirus entry comprises the initial virus attachment to a cellular receptor, then internalization through an endocytic process which includes virion uptake into vesicles followed by transport to late endosomes where a low pH-dependent fusion of viral and endosome membranes is triggered by GP2, and finally, the release of viral nucleocapsids to the cytoplasm. Different cellular receptors and entry pathways are used by distinct arenaviruses. OW viruses, such as LASV, LCMV, Mopeia virus (MPOV) and Mobala virus (MOBV), and clade C NW viruses bind to α -dystroglycan (α DG), an extracellular glycoprotein expressed in the matrix of a variety of tissues and cells (Cao et al., 1998; Spiropoulou et al., 2002). For the more recently emerged pathogenic OW LUIJV, another initial receptor was reported, the neuropilin (NRP)-2 receptor (Raaben et al., 2017). GP1 of clade B NW arenaviruses binds to transferrin receptor 1 (TfR1) to initiate infection, with recognition of the human protein for pathogenic viruses and TfR1 orthologs from other host species for the nonpathogenic ones (Radoshitzky and Abraham, 2007; Radoshitzky et al., 2008) whereas the receptor for clades A and D is not well elucidated. More recent studies have reported the involvement of other host components, like the C-type lectins DC-SIGN/L-SIGN (Goncalves et al., 2013; Martinez et al., 2013), the phosphatidylserine receptors Axl (Fedeli et al., 2018) and TIM-1 (Brouillette et al., 2018), suggesting the existence of multiple co-receptors or alternative receptors when the main primary receptor, α DG or TfR1 for OW or NW viruses, respectively, is absent.

After binding, NW viruses are endocytosed through a clathrin-mediated pathway and OW members enter through a nonclassical clathrin-independent route guided by the endosomal sorting complex required for transport (ESCRT) proteins (Martinez et al., 2007; Rojek et al., 2008; Pasqual et al., 2011). Recent studies also indicated a macropinocytosis pathway as possible entry route for OW arenaviruses (Oppliger et al., 2016). Additionally, a crucial host factor has been demonstrated for LASV infective entry: at the endosomal acidic pH LASV undergoes a receptor switch leaving α DG and binding to lysosomal associated membrane protein 1 (LAMP-1), a protein interaction that is essential for membrane fusion (Cohen-Dvashi et al., 2016; Jae et al., 2014). In OW and NW arenaviruses, the pH-activated fusion between virion and endosome membranes is triggered by GP2, a class I fusion protein, and modulated by the interaction of GP2 with SSP, an essential requirement to complete the viral penetration process (Nunberg and York, 2012).

Transcription and replication

The presence in the cytoplasm of the arenavirus genome closely associated to NP and L proteins, in a replicative complex designed RNP, is the only requirement to start macromolecular biosynthesis (Hass et al., 2004; Lee et al., 2000; López et al., 2001). The hallmark of transcription and replication in arenaviruses is the ambisense coding strategy of both RNA fragments. The S RNA encodes NP protein at its 3' portion in the genome complementary sense and the glycoprotein precursor GPC at the 5' portion in the genome sense whereas the L RNA encodes the L protein at the 3' portion and the Z protein at the 5' end in opposite orientations (Fig. 2). Although S and L genome segments contain protein coding sense sequences at their 5' regions, they are not directly translated and thus, arenaviruses behave as true negative strand viruses with transcription as the first biosynthetic process after uncoating.

The ambisense arrangement and the structural characteristics of genomes provide a mechanism for temporal regulation of transcription and replication. Primary transcription of the mRNAs for NP and L proteins from S and L genomes is the initial event followed by translation of both proteins (Fig. 2). The mRNAs of the arenaviruses have cap at the 5' end but are not polyadenylated at 3' end and the 5' cap is derived from cellular mRNAs. L protein has the RNA dependent RNA polymerase activity as well as an endonuclease activity required for cap-snatching from 5' end of host mRNAs to prime the initiation of viral transcription (Morin et al., 2010). The intergenic region (IGR) in both fragments folds into a hairpin configuration that is thought to serve as a transcription termination signal, leading to the release of the viral polymerase (López and Franze-Fernández, 2007; Pinschewer et al., 2005). Furthermore, the 3' and 5' untranslated regions (UTR) are complementary in each genome fragment generating a panhandle structure, important to regulate transcription, replication and translation (Foscaldi et al., 2017; Perez and de la Torre, 2003). After NP synthesis has occurred, replication would proceed via the synthesis of full-length antigenomic RNAs and then genomic RNAs (Fig. 2), both tightly recovered by NP as RNPs. The switch from transcription to replication involves the bypass of the hairpin-dependent termination signal and is mediated at least by the intracellular level of NP that functions as a transcriptional antiterminator through its interaction with the IGR sequence (Tortorici et al., 2001). The later event in arenavirus macromolecular biosynthesis is the transcription of subgenomic mRNAs for GPC and Z, respectively, from the antigenomic S and L RNAs, respectively, and their translation (Fig. 2).

Fig. 2 Ambisense genome strategy for transcription and replication of the two RNA fragments of arenaviruses. Each RNA fragment, L and S, encodes the genetic information for the synthesis of two polypeptides in opposite sense.

Assembly and budding

GPC glycosylation and cleavage take place in the endoplasmic reticulum and the trans-Golgi network by cellular enzymes to generate the mature GP1, GP2 and SSP proteins that are transported and inserted into the cell plasma membrane (Burri et al., 2012). As it is usual for enveloped negative stranded viruses, the assembly and budding of the viral particles is totally dependent on the matrix Z protein that directs the recruiting of the viral components at the plasma membrane regions enriched in viral GP. To this end, Z interactions with L, NP and GP have been demonstrated to assess their colocalization for virion assembly as well as the interaction of Z with the ESCRT proteins to drive the last step of the viral cycle: the exit of virions from the cell by budding at the plasma membrane (Loureiro et al., 2012). The only expression of Z in a cell, without the presence of either the viral genome or any other viral protein, was able to produce the budding of viral-like particles (Strecker et al., 2003; Urata et al., 2009). The formation of these particles empty of genome and packaged by a lipid cell membrane containing Z, confirms the key function of the matrix protein in arenavirus morphogenesis.

The human disease: Pathogenesis and immune response

Pathogenesis

LASV and JUNV cause the prototypical manifestations of human disease for the OW and NW mammarenaviruses, respectively. With an incubation period of 2–21 days for LASV and 6–14 days for JUNV, about 80% of the infections with these viruses turn out to be either asymptomatic or include flu-like symptoms, such as fever, malaise, headache, conjunctivitis, nausea, vomiting, and diarrhea. This makes it difficult to provide an accurate diagnosis unless there is evidence of a known outbreak (Kerber et al., 2015). These symptoms last from 7 to 10 days, after which approximately 75% of the patients start showing signs of improvement; while the remaining 25–30% shows a progression of the illness with the development of hemorrhages and neurological disorders in addition to fever (McCormick and Fisher-Hoch, 2002). Studies in rodent and human survivors of mammarenavirus infection indicate that the proper functioning of innate and T-cell mediated immune responses is critical to minimize viral growth rates, symptoms appearance, and mortality rates (Meyer and Ly, 2016). Monocytic cells such as alveolar macrophages and dendritic cells are the first viral targets; however they are not activated after viral entry as is reflected by the lack of increase in levels of activation markers and cytokines (Baize et al., 2004). This is consistent with the generalized immunosuppression seen in individuals with severe and fatal infection. These cells would be acting as a “reservoir” and promoters of viral spread while entering the draining lymph nodes.

It is estimated that 20–30% of patients infected with LASV get hospitalized and recover, while about 2% of them pass away, presenting a very high viral load from the initial stages of the disease and maintaining an uncontrolled high viremia throughout the entire period of illness. The reason they cannot limit the spread of the virus is believed to be a marked immunosuppression and lack of adaptive immune response. Patients who progress to severe cases of LF can develop very prominent liver damage with platelet factors and heme degradation products such as biomarkers, bleeding, and neurologic involvement that can be fatal (Gale et al., 2017). Survivors present a high rate of neurological sequelae of which sensorineural deafness is the most frequent (Okokhere et al.,

2009). In LASV case as so as LCMV the neutralizing antibody response is very delayed, it is complement dependent and of poor quality.

The AHF has three well defined phases: prodromal, neurological-hemorrhagic, and convalescence. Without treatment, patients would develop severe symptoms characterized by bleeding, vascular damage, petechiae in the oral mucosa, chest, arms, and axillary region, gingival bleeding, leukopenia, thrombocytopenia, ataxia, mental confusion, increased irritability, tremors that can progress to seizures, shock, bacterial infections, and coma (Enríá et al., 2008). Bleeding seems to be the result of the simultaneous occurrence of thrombocytopenia, abnormal platelet function induced by a plasma component, and alterations in blood coagulation with activation of fibrinolysis (Enríá et al., 2011). At the immunological level, AHF is characterized by an acute transitory immunodeficiency: cell-mediated immunity is depressed as evidenced by the decreased levels of delayed-type hypersensitivity to nonviral recall antigens and of lymphocyte proliferation stimulated by mitogens, as well as by marked changes in the T-cell subpopulations. There is also a lag in the humoral immune response, with antibodies appearing during the second week of illness, coincident with recovery. In contrast with LASV and LCMV, patient survival is characterized by a robust and persistent neutralizing antibody production which ultimately results in viral clearance.

On the other hand, a typical LCMV infection is characterized by two phases, a period of fever and viremia which is followed by a central nervous system (CNS) phase without virus circulation, but antibodies can be found in serum (Lehmann-Grube, 1972). The majority of the infections are subclinical, some of them consist of fever alone, and others show both the initial febrile state and the CNS disease, often with a short afebrile remission between both episodes. On those patients presenting clinical manifestations the disease may begin with fever, malaise, myalgia, gastrointestinal symptoms, and occasionally sore throat or cough. Arthralgia, testicular pain, parotid pain, may occur as well. During this phase, which may last from a few days to 2–3 weeks, leukopenia, lymphopenia, thrombocytopenia, and elevation of lactate dehydrogenase and aspartate aminotransferase levels are also observed. The neurologic stage begins with aseptic meningitis. Headache may be severe and disturbances of consciousness may be seen. Signs of nervous system involvement may last 1–4 weeks and resolve without sequelae. Rarely, encephalitis may occur with a very occasional fatal outcome (Enríá et al., 2011). The neurologic disease is thought to be immunopathologic and mediated by CD8+T cells because immunosuppressed patients infected with LCMV did not develop CNS symptomatology (Kang and McGavern, 2008). Convalescence may last several weeks with asthenia, febrile sensations, memory difficulties, poor cognitive function, headaches, or arthralgia.

Immune response

Virus-host interactions have evolved to enable viruses to resist or avoid host antiviral responses. Viral infection usually produces pathogen-associated molecular patterns (PAMPs) during viral replication that are easily recognized by immune cells. These PAMPs can be detected by host pattern recognition receptors, including retinoic acid inducible gene 1 (RIG-1)-like receptors, Toll-like receptors (TLR), and protein kinase receptors (PKR), activating downstream signaling pathways that stimulate an antiviral response in the form of the up-regulation or expression of type I interferons (IFN- α and IFN- β), cytokines, proapoptotic factors and the activation and maturation of innate immune cellular arms such as dendritic cells, T cells and macrophages (Jensen and Thomsen, 2012).

Although OW and NW viruses generate a few similar clinical symptoms, both groups show many differences at an immune response level. Moderate to severe symptoms in LASV infected patients are associated with inhibition of the innate immune response with decreased levels of IFN-I and pro-inflammatory cytokines such as tumor necrosis factor alpha (TNF- α) and a lack of neutralizing antibody presence, leading to the subsequent deficiency in stimulation of T cells, dendritic cells and macrophages (Brisse and Ly, 2019). Many of the mediators activated in septic shock are involved in the pathogenesis of LASV such as sulfidopeptide leukotrienes, catecholamines, platelet-activating factor and endorphins (Mahanty et al., 2003). In contrast, NW mammarenaviruses and LCMV tend to produce increased levels of IFN-I and cytokines during the acute period. JUNV and MACV do not suppress the innate immune mechanisms but shift towards a pro-inflammatory response involving an up-regulation of IFN- α and TNF- α , probably correlated with the severity and fatal outcome in NW infections (Enríá et al., 2011). For LCMV, clearance of acute infection is due to the robustness of the IFN response early during infection, prior to a peak in viral titer. The more substantial an IFN response is in the early stages of infection, the more likely it is that virus-specific CD8+ cytotoxic T cells will be induced and virus clearance will occur, whereas a weaker IFN response leads to the observed chronic and persistent LCMV infections in mice (Meyer and Ly, 2016).

Immune responses to arenavirus infections are modulated by the arenavirus multifunctional proteins NP and Z that control the antiviral response to infection by targeting multiple cellular pathways. The most important role of NP in pathogenesis is the inhibition of IFN-I and this role is largely mediated by its C-terminal exonuclease domain that was reported to prevent the potentiation of RIG-I function (Shao et al., 2018) and the activation of interferon regulatory factor 3 (IRF-3) and downstream genes (Hastie et al., 2011). The 3′–5′ exonuclease function of NP also possess high specificity for degradation of small dsRNAs triggering host defenses as the PKR pathway to halt viral replication and the downstream phosphorylation of the eukaryotic translation initiation factor 2 α (eIF2 α) to inhibit host and viral protein translation (García et al., 2006; King et al., 2017). Furthermore, immunosuppression mediated by NP-exonuclease activity also was shown to prevent the activation of natural killer cells (Wauquier et al., 2019). Other NP host interaction partner is the DEAD (Asp-Glu-Ala-Asp)-box ATP-dependent RNA helicase (DDX3), a protein that exhibits a proviral role for arenaviruses and acts as a transcriptional regulator of IFN- β promoter. NP may therefore promote viral spread by sequestering DDX3 from macromolecular complexes, and so suppress IFN-I induction subverting

immunity (Loureiro et al., 2018). An additional role of NP in infected cells is the inhibition of apoptosis, a cell process to induce their own death in response to cellular stress and damage caused by invading pathogens (Wolff et al., 2013).

Z is the other viral protein involved in arenavirus innate immune suppression and virulence through various protein-protein interactions. Z protein of the human pathogenic OW and NW strains can interact directly with RIG-1 to inhibit IFN-I expression, but Z of nonpathogenic viruses cannot (Fan et al., 2010; Xing et al., 2015). The proline-rich homeodomain (PRH), a cellular transcription factor with antiproliferative effects, is downregulated by Z protein of pathogenic viruses (Djavani et al., 2005). Z also binds to the translation initiation factor 4E (eIF4E), crucial for mRNA transport, transcript assembly onto polysomes and initiation of translation, affecting protein production (Campbell Dwyer et al., 2000). Z may also have a role in abrogating apoptosis induced upon infection through its interaction with the promyelocytic leukemia protein (PML), a regulator of cell growth involved in a number of apoptosis related pathways. After binding, Z produces PML redistribution from nuclear bodies to cytoplasmic bodies (Meyer and Groseth, 2018). Further, PML and Z bind to ribosomal P proteins in the nucleus thereby implying a role in regulating protein translation (Borden et al., 1998).

Another way in which arenaviruses may activate the innate immune system and promote an IFN-I response is through the activation of various TLRs (Vidya et al., 2018). NW and OW seem to have also diverged in this mechanism as JUNV induces activation of TLR 2 (Cuevas and Ross, 2014) while LCMV produces a TLR 7 and TLR 9 mediated response (Buechler et al., 2015).

Host restriction factors represent cellular proteins that interfere with specific steps of the viral multiplication cycle to inhibit infection. Many of these factors are IFN inducible and few of them have been shown to limit arenavirus entry and exit processes, such as gamma-interferon-inducible lysosomal thiol reductase (GILT), viperin and tetherin. GILT is a soluble enzyme that is highly expressed in the endosomal and lysosomal compartments blocking viral fusion and genome release (Chen et al., 2019) while viperin and tetherin have been shown to negatively affect arenaviral assembly and budding (Peña Cárcamo et al., 2018; Zadeh et al., 2020).

Lastly, the autophagy pathway is an important component of host antiviral defense, functioning to degrade pathogens and trigger both innate and adaptive immunity. During arenavirus infection, both OW and NW arenaviruses may utilize components of the autophagy pathway to aid in replication (Baillet et al., 2019; Perez Vidakovics et al., 2019; Roldán et al., 2019). However, the biological significance of this interaction of viral proteins with components of autophagy remains unknown.

Treatment and antiviral development

Treatments are very limited for the HF-causing arenaviruses (Fig. 3). Current antiviral therapies are restricted to the administration of either passive antibodies through transfusion of convalescent plasma for AHF patients (Enríá et al., 2008), or the off label use of the nucleoside analog ribavirin (1- β -D-ribofuranosyl-1,2,4-triazole-3-carboxamide) which has proven to be effective in treating LF patients (McCormick et al., 1986). More recently, favipiravir has also been used under compassionate use program to treat LF as well as AHF (Raabe et al., 2017; Veliziotis et al., 2020).

Convalescent plasma therapy has been in use for over a century as both post exposure prophylaxis and treatment, and is one of the best therapies currently available to treat COVID-19 (Bloch et al., 2020). However, critical parameters such as the timing of the treatment and the administered dose (volume and antibody titer levels) need to be adjusted. A successful example of this approach is the standard dose of JUNV-neutralizing antibodies provided by the National Institute of Human Viral Diseases of Argentina to treat infected patients which has shown to decrease the mortality rate from 30% to 1% if initiated within the first 8 days of disease (Enríá et al., 2008). An important drawback of this therapeutic approach is the exposure to transfusion-associated diseases and the development of late neurological complications in 10% of treated patients. This post-AHF neurologic syndrome occurs after a symptom-free period and is characterized by fever, cerebellar signs, and cranial nerve palsies. Finally, this therapy is highly specific for AHF since treatment of LF with convalescent serum was not effective in a clinical trial (McCormick et al., 1986).

As the availability of immune plasma from convalescent AHF patients may be limited, researchers have been putting their effort into alternative immunotherapeutic agents. The use of anti-TfR1 antibodies has been explored (Helguera et al., 2012), and recently Cohen-Dvashi et al. (2020) proposed the use of immunoadhesins as an attractive approach for fighting infections by TfR1-tropic mammarenaviruses. Moreover, Pan et al. (2018) have reported the generation of mouse monoclonal JUNV neutralizing antibodies. Recently, by vaccinating horses with vesicular stomatitis virus pseudotypes bearing JUNV GP, IgG antibodies were obtained that showed some cross-neutralization against pathogenic NW arenaviruses (Pan et al., 2020). Also in this context, other groups have explored different strategies (Amanat et al., 2020); however, further *in vivo* evaluation of all these immunotherapeutic agents is necessary.

On the other hand, arenaviral therapies using synthetic compounds have been historically ignored by pharmaceutical companies due to their limited profitability. Ribavirin is a broad spectrum antiviral approved for the treatment of hepatitis C virus and respiratory syncytial virus. It is a guanosine analog that directly inhibits RNA-dependent RNA polymerase, host inosine monophosphate dehydrogenase and viral capping enzymes (Graci and Cameron, 2006). In addition, there is also evidence that ribavirin causes viral mutagenesis as well as inhibition of viral replication (Moreno et al., 2011). Remarkably, ribavirin is the only drug shown to be effective for the treatment of LF in clinical trials decreasing mortality from 55% to 5% but only if its administration started within 6 days of symptoms onset (Attinsounon et al., 2018; McCormick et al., 1986). However, subsequent observational studies have shown mortality rates of 45% among treated patients (Shaffer et al., 2014). It must be noted that ribavirin is currently recommended for high risk exposures only, as it can induce adverse side effects such as thrombocytopenia, anemia, and birth

Fig. 3 Mammarenavirus multiplication cycle and antiviral targets. The steps of the viral cycle are depicted together with the corresponding therapies in clinical use and the antiviral agents under research: currently used therapies (letters in black and bold) and drug under compassionate use (letters in black and italics), experimental immunotherapeutic agents (letters in blue), and experimental natural and synthetic compounds (letters in green).

defects. Although treatment of LF with convalescent serum was not effective in a clinical trial, the efficacy of ribavirin when given as post-exposure prophylaxis was enhanced by concurrent treatment with convalescent serum (Jahriling et al., 1984). Unfortunately, ribavirin has been shown to be only marginally effective for the treatment of AHF (Enríá et al., 2008). Later reports have described the efficacy of different doses and treatment schedules of ribavirin tested in a guinea pig lethal model of JUNV infection (Salazar et al., 2012), and recently, modified ribavirin analogs were reported to have comparable *in vitro* effective concentration against JUNV, but with a higher selectivity index (Contin et al., 2019). However, no trials have been performed due to difficult recruitment of patients, inadequate supplies and the high drug cost.

The limited target market represented by arenaviruses restricts commercial interest and makes drug repurposing and/or the identification of broadly acting inhibitors targeting common mechanistic features of these viruses (or their interactions with the host) highly attractive approaches for therapeutic development. In addition, these strategies would simplify therapy in resource limited areas by allowing treatment initiation for clinically similar diseases that occur frequently within the same geographic region in advance of a detailed molecular diagnosis, which indeed may not always be available. Also, compounds with such a broad activity spectrum would in theory also be expected to target newly emerging viruses, such as the latest arenavirus isolates identified in recent years. In this sense, the era of large-scale screening made possible the random exploration of a broader number of compounds which brought the discovery of some interesting active molecules (Sudhakar et al., 2020). A screening of 11,968 compounds from a drug repurposing library (Repurposing, Focused Rescue and Accelerated Medchem [ReFRAME]) identified several potent inhibitors of LCMV, LASV and JUNV. The findings indicated that enzymes of the rate-limiting steps of pyrimidine and purine biosynthesis play critical roles in the completion of the mammarenavirus multiplication cycle, suggesting they represent potential druggable targets to counter human pathogenic infections (Kim et al., 2019). These results are in concordance of previous and recent studies reported from different groups, where some interesting broad compound candidates such as the inosine monophosphate dehydrogenase inhibitor AVN-944 (Dunham et al., 2018) and the dihydroorotate dehydrogenase inhibitors A771726 (Sepúlveda et al., 2018), KP-146 (Miranda et al., 2018), brequinar and other new investigational drugs (Kim et al., 2020) demonstrated promising anti-arenaviral activity.

An example of success of a broad antiviral compound is the anti-influenza drug favipiravir (T-705) which proved to be also efficacious against many other RNA viruses, including LASV and other OW arenaviruses in animal models (Mendenhall et al., 2011; Rosenke et al., 2018). Hickerson et al. (2018) have demonstrated complete protection against mortality and dramatic reduction in viral load in a mouse model of acute and disseminated LCMV infection after favipiravir treatment whereas ribavirin was mostly ineffective. These findings support the consideration of favipiravir as a first-line therapeutic option in organ transplant recipients, a target group at substantial risk to LCMV infection. Moreover, favipiravir significantly decreased mortality if given intraperitoneally in a guinea pig model of JUNV (Gowen et al., 2013). One of the mechanisms of action proposed for this drug is its incorporation into nascent single-strand RNA with the consequence loss of the RNA-NP interaction, leading the viral genome more accessible to cellular ribonuclease (Omotuyi et al., 2019). As previously mentioned, in January 2020 a case of imported AHF was reported in Belgium in a woman not engaged in agricultural activities, but somehow she got infected a few days before her trip from Argentina to Europe (Veliziotis et al., 2020). After confirmation of JUNV infection by real-time PCR, ribavirin was given first orally and then intravenously on day 6 after symptoms onset. The next day, due to its proven synergistic antiviral activity against JUNV in animal models (Westover et al., 2016) and previous experience with LF (Raabe et al., 2017), oral favipiravir was given through a nasogastric tube. Ribavirin therapy was discontinued on day 9 due to secondary effects and the dose of favipiravir was progressively increased during 14 days. Fortunately, the patient was discharged from the hospital after 50 days without sequelae. Although it was only one case report, it has demonstrated the importance of academics studies in the advance of the arenavirus antiviral field.

Regarding basic antiviral research, several groups have been focused on novel strategies during the last few years, targeting the viral entry with natural products like tangeretin (Tang et al., 2018) or different types of synthetic compounds like aptamers (Maier et al., 2016), the calcium channel blocker lacidipine, the synthetic pyrethroid pesticide phenothrin (Wang et al., 2018), the enzymes p38 α / β mitogen-activated protein kinases inhibitor losmapimod (Zhang et al., 2019a,b) and the anti-influenza drug arbidol (Hulseberg et al., 2019). Other type of promising compounds are blockers of the low-pH-induced membrane fusion as the adamantyl diphenyl piperazine 3.3 (Wang et al., 2018) and the 4-acyl-1,6-dialkylpiperazin-2-one (Plewe et al., 2019), and small molecules like LHF-535 (Madu et al., 2018), ST-161 (Zhang et al., 2019a,b) and clotrimazole derivatives like TRAM34 (Torriani et al., 2019). Some of these compounds are under phase I human safety studies. Compounds targeting the endonuclease domain of the L protein, required for arenavirus transcription, were also recently described as a new type of arenavirus inhibitors (Saez-Ayala et al., 2019). Hopefully, follow up of these studies (Fig. 3) will be reported in a near future.

Vaccines

Candid#1 vaccine

Currently, there are no vaccines licensed by the Food and Drug Administration (FDA) in USA to protect against arenavirus infection. The only clinically successful anti-arenaviral vaccine is the anti-JUNV Candid#1 strain, which is manufactured at a dedicated facility fully supported by the Argentinian government (Ambrosio et al., 2018). This vaccine developed through a joint international effort is a live attenuated vaccine derived from JUNV XJ44 parental strain, so designated to define the XJ prototype strain, the first JUNV clinical isolate from a human fatal case (Parodi et al., 1958), after two passages in guinea pig and 44 passages in mouse brain (Ambrosio et al., 2011). The XJ44 strain was serially passaged in fetal rhesus lung cells to get Candid #1, the first vaccine produced and registered under Argentina regulations since 2003.

Following a single intramuscular injection, Candid#1 proved to induce JUNV specific antibodies in 91.1% of the vaccinated population and a protective response of 95% against AHF. Its administration had a remarkable impact on the magnitude of JUNV epidemics in Argentina reducing the number of annual cases (Ambrosio et al., 2011; Maiztegui et al., 1998). The efficacy of Candid#1 vaccination is in accordance with the main role of JUNV neutralizing antibodies against GPC for clearance of the virus (Seregin et al., 2010), as also commented in the previous section. Neutralizing antibodies effectively target GP1 pocket which accepts the tyrosine residue of the cellular receptor TfR1 (Mahmutovic et al., 2015).

Whereas a number of unique mutations in Candid #1 were originally thought to attenuate the virulence of its parental strain (Chiringhelli et al., 1997; Goñi et al., 2006, 2010), further studies have identified a single mutation (F427I) in the transmembrane domain of GP2 to be the cause of reduced infectivity (Albariño et al., 2011). While the mechanism for this attenuation has yet to be elucidated, it is thought that the mutation may affect viral fusion or maturation efficiency. On the other hand, additional evidence suggests that at least one additional mutation in GP likely contributes to the attenuation in dissemination and virulence during infection (Seregin et al., 2015). It has also been suggested that the loss of an N-glycan in GP1 of Candid #1 could also contribute to *in vivo* attenuation, turning the vaccine strain more antigenic and therefore more susceptible to neutralizing antibodies (Sommerstein et al., 2015).

Other vaccine developments

Over the years, diverse strategies have been used in order to design vaccines for HF causing arenaviruses. Even though some showed protection in animal models, most of them have not been tested in humans. The earlier studies intended to get inactivated or live attenuated vaccines using classical protocols. Among inactivated vaccines, it was reported that the inoculation with formaldehyde-treated or gamma-irradiated LASV as well as formaldehyde-inactivated JUNV lead to an increase in specific antibodies but without conferring protection against viral challenge in animal models (Peters et al., 1987; Videla et al., 1989). In an attempt to obtain an

attenuated MACV strain to control BHF, as it was performed with JUNV, 60 serial virus passages were done in chick embryo cell cultures. Unfortunately, attenuation resulted insufficient and unstable, so those studies were abandoned (Peters et al., 1987). Furthermore, a preliminary report demonstrated some efficacy for Candid#1 against MACV infection in nonhuman primates, but the research has not continued to human trials.

Currently, various different approaches with new technologies and platforms are being implemented to obtain attenuated vaccinal strains of arenaviruses. Among the candidates showing efficacy in preclinical animal models, a live attenuated reassortment between LASV and MOPV, named clone ML29, was selected and tested as a vaccine in guinea pigs and rhesus macaques. ML29 has the S genome of LASV and the L genome of MOPV, a nonpathogenic OW arenavirus closely related to LASV (Lukashevich et al., 2005). Inoculation with this vaccine was followed by low levels of replication and transient viremia. Furthermore, small nonhuman primates showed protection against challenge with LASV and prevention of hepatic pathology (Lukashevich et al., 2008).

Reverse engineering was other strategy used to obtain an attenuated LASV strain. Cai et al. (2020) cloned the IGR of LASV S segment in the LASV L segment and co-transfected cells with this plasmid together with plasmids encoding LASV S segment, NP and L genes to produce recombinant viral particles. Guinea pigs inoculated with this virus, designed rLASV(IGR/S-S), showed no signs of infection and produced detectable levels of antibodies against LASV. Importantly, when challenged with wild-type LASV, animals were protected against the otherwise lethal virus.

Virus-like particles have also been used as vectors to develop vaccines. A recombinant vaccine based on vesicular stomatitis virus (VSV) vector that express the GPC of LASV was successfully assayed in two animal models of LF (Safronetz et al., 2015). Morbidity and mortality were fully prevented in guinea pigs and macaques vaccinated with this VSV-based strain and challenged with homologous and heterologous challenges of LASV. Recently, Johnson et al. (2020) used the human Venezuelan equine encephalitis vaccine (VEEV) as a basis to generate a vector that expressed both JUNV and MACV GPCs. While nonreplicative, this vector also guaranteed high immunogenicity due to high levels of expression of the viral GPCs specifically targeted. Guinea pigs inoculated with this vector developed specific neutralizing antibodies and showed protection when challenged with either virus.

During the writing of this manuscript, there were two vaccines against LASV registered in WHO's International Clinical Trials Registry Platform. One of them, MV-LASV is based on a proprietary replication-competent, live attenuated measles vector platform expressing LASV NP and GP (Purushotham et al., 2019). Developed by Themis Bioscience and the Institut Pasteur, it has shown protection in macaques after a single dose (Mateo et al., 2019) and since September 2019 its optimal dose, safety, tolerability and immunogenicity has been under evaluation in healthy volunteers. The second registered clinical trial aims to determine the safety, tolerability and immunological profile of the DNA vaccine INO-4500. This vaccine encodes the codon-optimized sequence of LASV GPC and it is administered by intradermal injection and posterior electroporation. Prior studies showed that INO-4500 provided protection and induced the production of neutralizing antibodies both in guinea pigs and macaques (Cashman et al., 2013, 2017) while research in humans has been planned to begin in August 2020.

Concluding remarks

Mammarenaviruses remain as a group of RNA viruses causing endemic diseases that represent a serious threat to human public health. Several factors are responsible of this challenging situation: the high case-fatality rate in patients with LF in Africa during the occurrence of annual outbreaks; the increase in the emergence of new viruses around the world in recent years as consequence of a regular search for the detection of virus, genome or antibodies, in rodents reservoirs; the risk of importation of HF arenaviruses outside of the endemic regions through increasing air travels. In fact, the isolation of new agents from severe human cases has been reported not long ago, underlining the urgent need of effective tools to combat these still neglected viral infections.

In spite of this critical situation, at present no specific safe chemotherapy or globally approved vaccines are available for most HF arenaviruses. Recent progress in the knowledge of virus-host interaction, at the molecular level of cell biology as well as at the multiple modulators of the complex arenavirus pathogenesis, will be helpful to improve the achievement of prophylactic or treatment alternatives. This effort will be further supported by the recent inclusion of LASV in the list of the WHO priority pathogens that require compelling clinical solution.

As with other viral diseases, vaccination was considered the most effective control strategy. A preventive vaccine, the live attenuated Candid#1, has been successful to control JUNV and reduce the incidence of HF in Argentina. A great effort has also been devoted to the development of a vaccine for LASV, with the implementation of diverse platforms based on recombinant arenaviruses, reverse engineering, plasmid DNA and vector viruses. Although several vaccinal strains have shown efficacy in the preclinical testing in animal models during the last 20 years, the initial phase I clinical trials in human volunteers for two LASV vaccine candidates has been just recently scheduled.

The only current treatment options for HF arenaviruses are the use of immune plasma or the nucleoside analog ribavirin, both presenting important limitations and undesirable side effects. Viral and host components essential for virus infection are the targets of several agents ongoing research. Hopefully, advances in understanding the detailed molecular biology of HF virus replication, coupled with determination of three-dimensional structures of viral molecules, could lead to the development of highly effective antiviral drugs against arenaviruses in a near future. The availability of arenavirus chemotherapy is mandatory since, even if successful vaccines against HF-viruses will be at hand, ecological changes in the habits of the rodent reservoirs as well as the appearance of new virus variants through genetic alterations cannot be discarded.

Glossary

Negative-stranded RNA virus A virus that uses negative sense, single-stranded RNA as its genome. The negative viral RNA is complementary to mRNA (positive sense).

Viral envelope The outermost layer of many kinds of viruses, typically derived from portions of the host cell membranes including some viral glycoproteins.

RNA-dependent RNA polymerase An enzyme that catalyzes the synthesis of RNA from an RNA template.

Neutralizing antibody An antibody that inhibits infection through binding to a pathogen.

Ribonucleoprotein complex (RNP complex) A complex of RNA and proteins that plays an integral part in regulating gene transcription and replication.

Niemann-Pick C1 (NPC1) protein The cholesterol transporter that has been shown to be a receptor that is essential for filovirus infection. Physiological function of NPC1 is involved in intracellular lipid transport and mutations in the NPC1 gene are known to cause Niemann-Pick disease, type C.

Innate immune system One of the two main immunity strategies found in vertebrates. It plays an important role in activation of the adaptive immune system through antigen presentation and cytokine production.

Natural host The living organisms in which an infectious agent naturally lives and reproduces.

Porcine reproductive and respiratory syndrome A swine disease caused by infection with an arterivirus (Porcine reproductive and respiratory syndrome virus).

Vesicular stomatitis virus (VSV) A virus in the family *Rhabdoviridae* that causes vesicular stomatitis in cattle, horses and pigs.

Antibody-dependent enhancement of infection A phenomenon in which a virus particle bound to antibodies enhances its entry into host cells.

Filovirus classification

Filoviruses are a family of non-segmented negative-stranded RNA viruses. Viruses in the family *Filoviridae* are phylogenetically divided into six genera: *Marburgvirus*, *Ebolavirus*, *Cuevavirus*, *Dianlovirus*, *Striavirus*, and *Thamnovirus* (Amarasinghe et al., 2019) (Table 1). The genus *Marburgvirus* has a single species with two known viruses (Marburg virus and Ravn virus). Six distinct species are currently known in the genus *Ebolavirus*: *Zaire ebolavirus*, *Sudan ebolavirus*, *Tai Forest ebolavirus*, *Bundibugyo ebolavirus*, *Reston ebolavirus*, and *Bombali ebolavirus*, represented by Ebola virus, Sudan virus, Tai Forest virus, Bundibugyo virus, Reston virus, and Bombali virus, respectively. The other genera in the family *Filoviridae* each have only one known species with one virus. Novel filoviruses (Bombali virus and Mênglà virus) were recently discovered and classified as a new ebolavirus species (*Bombali ebolavirus*) and new filovirus genus (*Dianlovirus*), respectively. The majority of ebolaviruses and marburgviruses are known to cause severe hemorrhagic fever (Ebola virus disease and Marburg virus disease) in humans and nonhuman primates, whereas Reston virus is believed to induce only subclinical infection in humans. Although infectious forms of the viruses in the *Cuevavirus* and *Dianlovirus* genera and the *Bombali ebolavirus* species have not been isolated, their complete genomes have been detected in bats. RNA genomes of the viruses in the *Striavirus* and *Thamnovirus* genera have been detected in fish. Due to their highly pathogenic characteristics, ebolaviruses and marburgviruses are classified as requiring biosafety level 4, the highest level of biocontainment for handling infectious viruses.

Table 1 Members of the family *Filoviridae*.

Genus	Species	Virus name	Known host (isolation or genetic detection)
<i>Ebolavirus</i>	<i>Zaire ebolavirus</i>	Ebola virus	Human, monkey, bat, duiker
	<i>Sudan ebolavirus</i>	Sudan virus	Human
	<i>Tai Forest ebolavirus</i>	Tai Forest virus	Human, monkey
	<i>Bundibugyo ebolavirus</i>	Bundibugyo virus	Human
	<i>Reston ebolavirus</i>	Reston virus	Monkey, pig, bat
	<i>Bombali ebolavirus</i>	Bombali virus	Bat
<i>Marburgvirus</i>	<i>Marburg marburgvirus</i>	Marburg virus	Human, monkey, bat
	<i>Marburg marburgvirus</i>	Ravn virus	Human, bat
<i>Cuevavirus</i>	<i>Lloviu cuevavirus</i>	Lloviu virus	Bat
<i>Dianlovirus</i>	<i>Mengla dianlovirus</i>	Měnglà virus	Bat
<i>Striavirus</i>	<i>Xilang striavirus</i>	Xīlāng virus	Fish
<i>Thamnovirus</i>	<i>Huangjiao thamnovirus</i>	Huángjiāo virus	Fish

Structure and viral protein functions

Filovirus particles are filamentous, enveloped by a host-derived lipid bilayer, and have an almost uniform diameter of approximately 80 nm. The filaments can be shaped like a “6,” a “U,” or a circle. The name “filovirus” is derived from this unique filiform structure (Fig. 1A). The filovirus RNA genome encodes at least seven structural proteins that comprise virus particles: a nucleoprotein (NP), polymerase cofactor (VP35), matrix protein (VP40), glycoprotein (GP), transcription activator (VP30), minor matrix protein (VP24), and an RNA-dependent RNA polymerase (L) (Fig. 1B and C) (Feldmann et al., 2013). Ebolaviruses produce nonstructural secretory GPs (sGP and ssGP), which are not produced by marburgviruses. The viral surface GP, which is responsible for the viral entry into cells (attachment to cell surface receptors and membrane fusion between the viral envelope and cellular

Fig. 1 Ebola virus particles, genes, and proteins. (A) Electron micrographs of Ebola virus particles. (B) Schematic diagrams of a filovirus particle. (C) Negative-sense genome organization.

membrane), is the only target for neutralizing antibodies. Although the function of the nonstructural GPs remains unclear, it has been suggested that they may act as decoys to interfere with neutralizing antibodies or as inhibitory factors against macrophage activation. The viral RNA, NP, VP35, VP30, and L form the ribonucleoprotein complex (RNP complex), which is involved in the transcription and replication of the viral genome. NP molecules form a helical nucleocapsid that contains the viral genome. VP40 is the key driving force for virus particle formation and budding from infected cells. Ebolavirus VP35 and VP24, and Marburgvirus VP35 and VP40 have been shown to be interferon antagonists (Messaoudi et al., 2015).

The entry of filoviruses into host cells is mediated by viral surface GP and initiated by the attachment of GP to cell surfaces (Takada et al., 1997). Virus particles are then delivered to endosomes by micropinocytosis, a mode of endocytosis (Nanbo et al., 2010; Saeed et al., 2010). During the entry into cells, filovirus GP interacts with several host cell receptors such as C-type lectins, T-cell immunoglobulin and mucin domain 1, along with Niemann-Pick C1 (NPC1) protein (Carette et al., 2011; Côté et al., 2011; Kondratowicz et al., 2011; Marzi et al., 2004; Simmons et al., 2003; Takada et al., 2004). Of these receptor molecules, NPC1 is known to be a critical factor for determining the host tropism of filoviruses (Ng et al., 2015; Takadate et al., 2020). The interaction between GP and NPC1 triggers fusion between the viral envelope and the endosomal membrane, leading to the release of the RNP complex into the cytoplasm. In the cytoplasm, each filovirus gene is transcribed into mRNA by the L protein (RNA-dependent RNA polymerase) and other viral proteins, such as VP35, and viral mRNAs are translated by the machinery of the host cell. The negative-sense RNA genome is also used to synthesize full-length complementary and antigenomic RNAs, which in turn serve as templates for viral genomic RNA synthesis. Newly synthesized viral proteins and genomic RNA are transferred to the cell surface for incorporation into viral particles. During the budding process, membrane-associated VP40 accompanying the viral surface GP extrudes from the cell membrane as a viral envelope and incorporates the RNP complex. Viral particles are then released by pinching off the plasma membrane.

Epidemics of filovirus diseases

Marburg virus was first discovered at the Philipps University of Marburg in Germany in 1967. Researchers and laboratory technicians showed symptoms of a hemorrhagic fever after handling samples from African green monkeys that had been imported from Uganda to Germany and the former Yugoslavia for research purposes. The virus was then isolated from the infected patients (Malherbe and Strickland-Cholmley, 1968). Ebola virus was discovered in 1976. In that year, outbreaks of hemorrhagic fevers with high mortality rates were confirmed in the Democratic Republic of the Congo (named Zaire at the time) and Sudan at around the same time. These hemorrhagic fevers were initially suspected to have been caused by Marburg virus. However, it was subsequently discovered that, although the shapes of the virus particles were highly similar, the virus was of a new genus. This genus was later given the name *Ebolavirus* (Johnson et al., 1977). Two species of the *Ebolavirus* genus were discovered independently in the Democratic Republic of the Congo and Sudan, currently named *Zaire ebolavirus* and *Sudan ebolavirus*, including Ebola virus and Sudan virus, respectively. Sporadic reports of outbreaks of infections caused by marburgviruses and ebolaviruses have continued in African countries such as the Democratic Republic of the Congo, Sudan, Gabon, the Republic of the Congo, Uganda, Cote d'Ivoire, Kenya, and Angola, alongside the discovery of new species in the genus *Ebolavirus*: *Tai Forest ebolavirus* and *Bundibugyo ebolavirus* found in 1994 and 2007, respectively (Fig. 2). In particular, the outbreak of Ebola virus disease that occurred in West Africa (primarily Guinea, Liberia, and Sierra Leone) in 2014 grew into an unprecedented epidemic that spread into neighboring African countries. In addition, a large number of infections were reported among medical personnel who had been involved in medical treatment in the affected region. Some of these personnel exhibited symptoms and were hospitalized after returning to Europe or to the United States of America, leading to the virus becoming a worldwide issue. Over the course of the epidemic, approximately 30,000 cases and more than 10,000 deaths were reported. The Ebola virus disease outbreak that occurred in the Democratic Republic of the Congo in 2018 also spread widely (but was mostly limited to that country) and became the second-largest epidemic of Ebola virus disease in history, with at least 3000 cases and 2000 deaths. Reasons for the spread of infection included delays in definitive diagnosis, outbreaks in densely populated areas, and political instability. These epidemics allowed research and development into prevention, treatment, and diagnostic methods relating to Ebola virus disease to be accelerated and unapproved vaccines and therapeutic agents to be clinically tested and advanced towards implementation.

Pathogenesis of filovirus diseases

Ebolaviruses and marburgviruses are highly pathogenic for humans and nonhuman primates. However, the pathogenicity differs depending on the virus species and variant. For example, Ebola virus has the highest mortality rate among ebolaviruses, sometimes close to 90%, whereas Reston virus is believed to induce only subclinical infection in humans (Feldmann et al., 2013). Clinical symptoms during the early stages of infection include fever, chills, fatigue, loss of appetite, nausea, diarrhea, and muscle pain, making it difficult to distinguish filovirus diseases from other febrile diseases such as malaria and influenza. Symptoms during the later stages of infection include those accompanying blood coagulation abnormalities, such as petechial hemorrhages and bleeding from mucous membranes. Pathobiological events during Ebola virus infection are summarized in Fig. 3. After entering the body from mucous membranes or wounds through a medium such as blood, mucus, or vomit, ebolaviruses primarily target antigen-presenting cells such as dendritic cells and macrophages, which are one of the main components of the innate immune system.

Fig. 2 Outbreaks of filovirus diseases in Africa. Affected countries, filovirus species, and years of outbreaks are shown.

Impeded function and/or hyperreaction of these cells plays an important role in the pathogenicity of the viruses (Geisbert and Hensley, 2004). Bystander apoptosis of lymphocytes is also observed, and the induction of adaptive immunity is also impaired by a significant reduction in their numbers (Baize et al., 1999). Lymphocytes themselves are insensitive to ebolaviruses and marburgviruses, suggesting that direct infection of lymphocytes may not be the cause. However, the detailed molecular mechanisms of the pathobiological events induced by filoviruses are largely unknown (Dolnik et al., 2008).

Hepatocytes are also known to be highly susceptible to the viruses and impairment of liver function results in elevated levels of liver enzymes in the blood (Feldmann et al., 2013). In the later stages of infection, the virus spreads throughout the body and disrupts the functions of many tissues. At the same time, hemorrhagic diathesis and multiple organ failure occur due to thrombocytopenia, cytokine storms (dysregulated cytokine production from large numbers of white blood cells), and vascular endothelial cell dysfunction. The variant of Ebola virus that caused the epidemics in West Africa from 2013 through 2016 belongs to the species *Zaire ebolavirus*; however, it was less pathogenic in experimentally infected animals than other Ebola viruses isolated previously and the hemorrhagic manifestation was not typically seen in many cases of human infection during the outbreak (Marzi et al., 2015; Schieffelin et al., 2014). The disease caused by ebolaviruses was originally known as Ebola hemorrhagic fever; however, in recent years it has come to be called Ebola virus disease, reflecting the fact that ebolavirus infection does not necessarily lead to a hemorrhagic symptom.

Ebolaviruses usually cause acute and fatal infections as described above, but there are some reports suggesting that persistent infections might also occur. Multiple studies carried out on patients who had recovered during the epidemics in the Democratic Republic of the Congo in 1995 and in West Africa between 2013 and 2016 suggested that the viral RNA genome could remain in the mucous tissues of the eye or in semen for up to 9 months (Deen et al., 2015; Varkey et al., 2015). However, given that only viral RNA was found and an infectious form of the virus was not isolated, it cannot be concluded that these recovered patients carried infectious forms of the virus over long periods or that they could infect others. Despite this, a case was reported in which an infectious form of the virus was detected in the cerebrospinal fluid of a nurse from the United Kingdom who recovered from Ebola

Fig. 3 Pathogenesis of Ebola hemorrhagic fever. Multiple detrimental pathobiological events occur during the infection.

virus infection and developed meningoencephalitis several months later. This could potentially be a case of persistent infection and reactivation of the virus (Jacobs et al., 2016). However, there is currently limited knowledge of the pathogenesis and mechanisms of its persistent infection due to the near 100% mortality rate for animal models of Ebola virus infection, and further research is required.

Susceptible hosts and transmission routes

For viruses such as ebolaviruses and marburgviruses, which cause infectious diseases with high mortality rates in some animal species, the existence of other animals that can maintain the virus for prolonged periods without acute or fatal disease is generally essential in order for them to survive in nature. Such animals are referred to as “natural hosts” or “natural reservoirs” of the virus. The virus is maintained within an individual or population of natural hosts over a long period of time. This is considered the natural form of virus perpetuation in nature. Such viruses maintained by their own natural hosts occasionally infect humans, in some cases fatally.

Some species of fruit bats have been considered to be the most likely natural hosts for ebolaviruses since the viral genomic RNA fragment (*Zaire ebolavirus*) and ebolavirus-specific antibodies were detected in fruit bats captured in the affected area during the large outbreak of Ebola virus disease among humans and great apes that occurred in Gabon and the Republic of the Congo between 2001 and 2003 (Leroy et al., 2005). Ebola virus-specific antibodies have also been detected in multiple species of fruit bats in subsequent studies (Ogawa et al., 2015; Pourrut et al., 2007), and Reston virus RNA fragment and/or antibodies that reacted to Reston virus were detected in insectivorous bats living in Asia (Jayme et al., 2015; Taniguchi et al., 2011). Bombali virus, a recently discovered species of ebolavirus, was detected in insectivorous bats in West Africa in 2018 (Goldstein et al., 2018). These observations clearly indicate that bats are susceptible to ebolavirus infection. However, in the past Ebola virus disease outbreaks, there has not been any compelling evidence showing that humans were infected with an ebolavirus by direct contact with bats. In addition to the fact that an infectious form of an ebolavirus has never been isolated from bats, almost all studies conducted so far have failed to even detect ebolavirus genomes in bats. Based on these observations, it cannot be proven that bats are a natural host for ebolaviruses. To provide epidemiological proof that bats are a natural host for ebolaviruses and are the source of infection for other animals, including humans, viruses that are genetically similar to those isolated from humans need to be detected or isolated from bats continuously over a prolonged period of time.

In the case of marburgviruses, it is highly likely that fruit bats living in caves retain the virus continuously and are a direct source of infection to humans. This is supported by the fact that multiple marburgviruses were continuously isolated from the tissue samples of Egyptian fruit bats (*Rousettus aegyptiacus*) (Fig. 4) living in a cave during the outbreak of Marburg virus disease among miners in Uganda in 2007 (Towner et al., 2009). The virus isolated from the bats was a strain that was almost genetically identical to the virus isolated from the infected people, demonstrating that a marburgvirus carried by the bats had been transmitted to humans.

Fig. 4 A fruit bat (*Rousettus aegyptiacus*) captured in Africa. Marburgviruses are frequently found in these cave-dwelling fruit bats.

In 2007 and 2008, travelers from the United States of America and the Netherlands who had been visiting a cave in Uganda began to show symptoms of Marburg virus disease after returning to their home countries, and Marburg viruses were isolated from bats captured in the cave (Amman et al., 2012).

There have been several cases so far of humans contracting Ebola virus disease or Marburg virus disease through direct contact with infected monkeys. However, nonhuman primates are not considered natural hosts for filoviruses because they are thought to develop severe infectious diseases with high mortality rates when infected with ebolaviruses or marburgviruses as indicated by natural and experimental infections of them with these viruses. Nevertheless, seroepidemiological studies have demonstrated filovirus-specific antibodies in primates, including humans (Becker et al., 1992; Leroy et al., 2004), and shown that susceptibility to ebolaviruses varies among species and among individual monkeys. This means that there is a possibility of frequent occurrences in nature among certain species of monkeys that experience subclinical or non-lethal filovirus infection. Clinical cases of persistent infection in humans have also been observed (Jacobs et al., 2016). If filoviruses with low pathogenicity among primates exist in nature and only viruses that have acquired a certain mutation exhibit high pathogenicity, or if a known virus with high pathogenicity frequently results in non-fatal infections of a particular species of monkey or individual monkeys, the possibility that monkeys could be a natural host for filoviruses cannot be ruled out.

There have also been reports of tetrapods being naturally infected with filoviruses. Reston virus was unintentionally isolated from pigs with porcine reproductive and respiratory syndrome in the Philippines in 2008 and 2009 (Barrette et al., 2009). This virus was subsequently detected in pigs with the same disease in China. However, although Reston virus has been shown to be highly pathogenic among monkeys, its pathogenicity for humans and livestock has not been established. Previous reports have suggested that Reston virus only induces subclinical infections in humans and pigs. On the other hand, it has been confirmed that duikers, of the Bovidae family, were infected with Ebola virus during the epidemic in Gabon and the Republic of the Congo between 2001 and 2003, where large numbers of great apes such as gorillas and chimpanzees succumbed to the infection in the forest. There have also been reports that about 25% of dogs living in the villages that had experienced an epidemic of Ebola virus disease had Ebola virus-specific antibodies (Allela et al., 2005). Since various animal species are considered to be susceptible to filoviruses, as described above, livestock and wild animals could be intermediate hosts, and direct sources for filovirus transmission to humans.

Distribution of filoviruses

Ebola virus disease and Marburg virus disease mainly occur in Central Africa. However, marburgviruses have been detected in fruit bats (*R. aegyptiacus*) in African countries other than those where outbreaks and/or patients with the diseases have been reported (Amman et al., 2020; Kajihara et al., 2019; Pawęska et al., 2018). Indeed, it has been predicted that filoviruses may exist across the Afrotropics (Peterson et al., 2004). More interestingly, the presence of Reston virus has also been confirmed in Asia (Philippines and China). In addition, Mënglà virus, a filovirus of the recently-recognized genus *Dianlovirus*, has been detected in bats in southern China (Yang et al., 2019). With that being said, the presence of filoviruses has also been suggested or confirmed in countries outside of Africa, the Philippines, and China. For example, filovirus-specific antibodies have been detected in the sera of orangutans in Indonesia, humans (bat hunters) in India, and bats in India, Singapore, and Bangladesh (Dovih et al., 2019; Laing et al., 2018; Nidom et al., 2012; Olival et al., 2013). Reston virus is the only filovirus to have been confirmed in Asia; however, in many cases the

detected antibodies were specific to other ebolaviruses that have not been discovered outside of Africa to date. Antibodies against various filoviruses have also been detected in bats in China (Zhang et al., 2020). In Europe, Lloviu virus, of the genus *Cuevavirus*, was discovered in bats that died as part of mass fatalities that occurred among insectivorous bats in caves in France, Spain, and Portugal (Negredo et al., 2011). The discovery of Xīlǎng virus and Huángjiāo virus (*Striavirus* and *Thamnovirus* genera, respectively) in fish (frogfish and filefish) in China is also of interest (Shi et al., 2018). These reports suggest that filoviruses are distributed over a wide area that includes Asia and Europe, and that multiple filovirus species, including unknown varieties, infect various animal species. However, it is unclear whether filoviruses other than ebolaviruses and marburgviruses are pathogenic to humans and nonhuman primates.

Animal models of filovirus diseases

Nonhuman primates such as rhesus and cynomolgus macaques and rodents such as mice and guinea pigs have been used as animal models for hemorrhagic fevers caused by filoviruses (Nakayama and Saijo, 2013). Nonhuman primates experimentally infected with ebolaviruses and marburgviruses show high susceptibility to filoviruses isolated from humans and exhibit clinical signs and pathologies similar to hemorrhagic fevers in humans. Ferrets are also used as experimental animals that exhibit pathologies similar to Ebola virus disease (Cross et al., 2016). However, infection of rodents such as guinea pigs and mice with virus strains isolated from humans does not cause lethal disease though they are susceptible to the viruses. The human-derived virus strains must be adapted through multiple passages in these animals, which accumulate several genetic mutations, before they can be used as an adapted virus strain to cause a lethal infection in these rodents. In addition, although the rodent-adapted filoviruses cause lethal infections of mice and guinea pigs, the blood coagulation abnormalities differ from those seen in primates, and these animal studies could thus be considered suboptimal as a method to elucidate the mechanism of the pathogenesis and determine the efficacy of vaccines and therapeutic agents. However, infection of hamsters with mouse-adapted viruses has been shown to cause a lethal disease more similar to Ebola virus disease in primates (Ebihara et al., 2013). At the same time, it is important to note that, even before adaptation to these rodents, filoviruses isolated from humans can replicate inside the body to some extent without causing disease, and pathogenicity to these animals is acquired with only a few genetic mutations that are most likely involved in interference with the innate immune system. The difference between lethal and subclinical infections is determined by a limited number of amino acid substitutions, and viral pathogenesis is generally controlled by the delicate balance between the proliferative capacity of the virus and the host immune response.

Vaccines and treatment

Following two large outbreaks in West Africa between 2013 and 2016 and in the Democratic Republic of the Congo between 2018 and 2020, research and development into prevention, treatment and diagnostic methods for Ebola virus disease were accelerated and various unapproved vaccines and therapeutic agents were clinically tested and advanced towards the practical use (Hoenen et al., 2019). The vaccines that underwent clinical testing during these outbreaks were based on recombinant viral vectors in which the gene of Ebola virus glycoprotein (GP), the target of neutralizing antibodies, was incorporated into other safe viruses. Although not approved at the time, vaccines using vesicular stomatitis virus (VSV) and combination of chimpanzee adenovirus and vaccinia virus as viral vectors were tested in humans (Ewer et al., 2016; Henao-Restrepo et al., 2015). The recombinant vesicular stomatitis virus-based vaccine was confirmed to be effective and safe, and was subsequently approved by the Food and Drug Administration in the United States of America. In general, a vaccine that uses a viral vector replicates in target cells and newly expresses exogenous viral antigens. For this reason, they are considered to be important for protective immunity because they efficiently activate the innate immune system and induce both neutralizing antibodies and cellular (e.g., cytotoxic T cell) immune responses.

Antibody therapy is the most effective therapeutic method in nonhuman primate models. However, the effectiveness of traditional passive immunization methods (administration of blood serum or plasma from humans who have recovered from the disease) was unclear in the past outbreaks in the Democratic Republic of the Congo. Passive immunization using plasma from patients who had recovered was also attempted during the epidemic in West Africa between 2013 and 2016, but beneficial effects were not evident. This might imply undesirable effects due to the presence of antibodies that cause antibody-dependent enhancement of infection (Takada and Kawaoka, 2003). Meanwhile, the efficacy of neutralizing monoclonal antibody cocktails has been proven in monkey models (Takada, 2013). During the Ebola virus disease epidemic in West Africa, a monoclonal antibody cocktail was used for the first time as an unapproved drug, and it was confirmed to be somewhat effective. Other antibodies were also used during the epidemic in the Democratic Republic of the Congo in 2018 and antibodies with even greater therapeutic effects have been found. However, the fact that the antigenicity of GPs varies substantially among ebolavirus species is a challenge that needs to be overcome in the development of vaccines and antibody therapies. The vaccines and therapeutic antibodies that have been developed so far are specific to Ebola viruses in the species *Zaire ebolavirus* and cannot be expected to be effective against other ebolaviruses. However, several antibodies exhibiting cross-neutralizing activities against multiple species of ebolaviruses have been discovered, and therapeutic effects have been confirmed in animal models (Flyak et al., 2016; Furuyama et al., 2016; Holtsberg et al., 2016). In the future, it is expected that a highly versatile therapeutic agent for Ebola virus disease will be developed using a cocktail of cross-reactive neutralizing antibodies. In addition to antibody drugs, several nucleic acid analog compounds, including those

developed as therapeutic agents for other viral infections, were used as emergency treatments during the Ebola virus disease epidemics in West Africa and the Democratic Republic of the Congo (Kupferschmidt and Cohen, 2015). Some of these compounds have potential as therapeutic agents and may be effective against multiple RNA viruses as broad spectrum inhibitors of RNA-dependent RNA polymerases (Furuta et al., 2005; Warren et al., 2016), although none of them has been approved for treatment of Ebola virus disease (as of June 2020).

Conclusion

For some time after their discovery, filoviruses were considered to be unique to Africa. However, the confirmed presence of filoviruses in Europe and Asia and the detection of filovirus genomes and virus-specific antibodies in some animals in areas where there have been no reports of outbreaks of filovirus infections suggest that unknown filoviruses may be present in a wider area, including in Asia. Alongside the development of effective vaccines and therapeutic agents, the elucidation of the ecology of the viruses in nature and the dissemination of simple and stable rapid diagnostic methods are essential to establish control measures against filovirus diseases. The former will prevent the virus transmission to humans, and the latter will enable appropriate containment measures through early diagnosis.

Introduction

Invasive fungal disease (IFD) is associated to high morbidity and mortality. Prolonged survival of patients with malignant diseases, as well as the increased number of patients undergoing solid-organ transplantation (SOT) and hematopoietic stem cell transplantation (HSCT) have significantly heightened the burden of patients “susceptible” to opportunistic infections. Similarly, the appearance and rapid development of new therapies like monoclonal antibodies and small-molecule inhibitors for autoimmune diseases and B-cell malignancies have further increased the pool of patients who might be susceptible to fungal infections. Finally, improvements in diagnostic tests and microbiology laboratories have resulted in a higher likelihood of diagnosing patients with fungal infection.

Over the last, few years, costs associated with fungal infections have increased significantly due to high costs in radiological techniques, microbiology labs and antifungal agents, especially. The widespread use of antifungal agents as both prophylaxis and treatment, and in agriculture has led to an increase in antifungal resistance. To add another element of complexity, antifungal agents are associated with significant short- and long-term toxicity; drug-drug interactions among antifungals, chemotherapy and immunosuppressive agents are a major concern. In this setting, a thorough evaluation of the risk of fungal infection in different populations is essential in assessing the requirement of antifungal prophylaxis, initiating prompt antifungal therapy in high-risk patients with suggestive clinical presentations, avoiding detrimental effects, costs, toxicities, and increasing antifungal resistance associated with the misuse of such agents.

Table 1 At-risk populations and overall risk factors for invasive candidiasis and invasive aspergillosis.

	<i>Invasive candidiasis</i>	<i>Invasive aspergillosis</i>
Risk factors	• Severity of disease • Age: <1 year or >65 years • Comorbidities: diabetes mellitus, chronic hepatopathy, malnutrition, etc. • Prior surgery (mainly abdominal) • Prolonged ICU stay • Invasive devices (urinary catheter, central vascular catheter, arterial catheter, etc.) • Total parenteral nutrition • Mechanical ventilation	• Neutropenia • Deficit of phagocytic function • Cellular immunity alteration • Corticosteroids use • Immunosuppressive drugs • Breach of mucocutaneous barriers • Environmental exposure
At-risk populations and interindividual conditions	• Long-term central vascular catheter • Broad-spectrum antibiotic • Prior <i>Candida</i> spp. colonization • Renal insufficiency and hemodialysis • Neutropenia • Chemotherapy, corticosteroids, and other immunosuppressants • Pancreatitis, visceral perforation, etc. • Critical care patients • Polytraumatic patients • Large burns • Newborns with a low gestational age, use of anti-H2, congenital malformations, gastrointestinal disease or shock	• Profound (<100/mm³) and prolonged (>10 days) neutropenia • Acute leukemia and myelodysplastic syndromes receiving induction or salvage chemotherapy • Allogenic HSCT presenting graft-vs-host disease requiring corticosteroids or suffering CMV infection • Solid organ transplant recipients: lung > heart > bowel > liver > kidney • HIV/AIDS without HAART and a CD4 count below 100/mm³ • Use of “biological therapies”: anti-CD52, Jak-kinase inhibitors, tyrosine-kinase inhibitors, anti-tumor necrosis factor, etc. • Critical care patients, especially patients with viral infections, such as influenza or COVID-19 requiring ICU admission • Patients with solid tumor and predisposing pulmonary lesions • Patients with COPD receiving corticosteroids

Abbreviations: ICU, intensive care unit; HSCT, hematopoietic stem-cell transplant; HIV, human immunodeficiency virus; AIDS, acquired immune deficiency syndrome; HAART, highly-active antiretroviral therapy.

The specific risk of a patient is determined by several different factors, including those associated with the baseline disease and treatment, factors intrinsic to the patient, and the environment. In this chapter, we will analyze risk factors for fungal infections per these factors and grouped in accordance with different high-risk populations.

In the last decade, we have overseen the emergence of fungi, such as *Cryptococcus*, *Trichosporon*, *Fusarium*, Mucorales and dematiaceous fungi. However, this chapter will mainly focus on invasive candidiasis and invasive aspergillosis, as these are the most frequent IFDs worldwide. Table 1 shows overall risk factors and populations at risk for invasive candidiasis and invasive aspergillosis.

Intrinsic and environmental factors associated with fungal infection

Age and comorbidities

Advanced age (with different cut-offs) has been associated with an increased risk of IFD and higher secondary mortality in various studies, particularly in hematological patients. Diabetes mellitus and hyperglycemia hinder innate immunity and have been linked with an elevated risk of IFDs, particularly for rhinoorbital mucormycosis. Deep hypoalbuminemia has also been found to be associated with a higher risk of IFDs in some studies and might be especially important for patients in the intensive care unit (ICU). Smoking was an independent risk factor for fungal infection in some studies, although some confounders may have existed. Patients with previously disrupted lung parenchyma, such as patients with previous tuberculosis or atypical mycobacterial infection, chronic obstructive pulmonary disease (COPD), bronchiectasis, sarcoidosis or lung cancer have a significantly increased risk of aspergillosis, more specifically with chronic and subacute forms. In these series of patients, there are prominent challenges, such as biomarkers are commonly negative, signs and symptoms are quite unspecific, and radiological imaging is quite different from that obtained from immunosuppressed patients.

In the last, few years, some prognostic scores in HSCT patients have been shown to correlate with the risk of fungal infection (Busca et al., 2018). However, performance of these scores in a non-transplant setting remains unknown.

Environmental factors

Molds are found in soil and decaying plant matter, contaminated water and building materials. As molds are usually airborne spread with inhalation and pulmonary involvement as the first compromise step, environmental factors that increase the number of spores in the environment have been related to a higher risk of IFD in susceptible hosts (Garcia-Vidal et al., 2014). Dry weather, high temperatures and some high-exposure activities such as gardening, construction or farming could also increase the risk of IFD caused by molds.

Within the context of a hospital setting, construction work in the hospitalization ward or even beside hospital premises could be responsible for an unusual increase in the incidence of IFD. Additionally, patients undergoing bone marrow transplantation who are hospitalized in rooms without laminar flow or high-efficiency filters are 5.6 times likelier to develop an IFD than patients hospitalized in rooms with such systems in place (Wald et al., 1997). That stated, a thorough anamnesis regarding potential exposures is paramount.

Treatments and manipulations

Chemotherapeutic agents and other new treatments for onco-hematological or autoimmune diseases will be commented upon in the following section. However, we will first present common risk factors that are mainly independent of baseline disease.

Most yeasts causing IFD in humans are commensals, residing in the oral cavity, gastrointestinal tract, and vaginal mucosa. The main risk factors for disseminated yeast infection (mainly candidemia) are as follows: (i) disruption of the cutaneous barrier mostly due to intravascular access devices (which may lead to catheter-related fungemia) but also as a result of deep wounds, ulcerations or burns; (ii) disruption of the mucosal barrier due to gastrointestinal tract surgery; (iii) alteration of normal bacterial flora due to broad-spectrum antibiotics (which leads to an overgrowth and predominance of yeast) and; (iv) total parenteral nutrition (lipid formulations favor fungal invasion).

Glucocorticoids inhibit neutrophil chemotaxis and oxidative bursts and debilitate macrophages' capacity to remove conidia (Stuehler et al., 2015). Consequently, glucocorticoids have been long recognized as an important risk factor for several different IFD, although it is not well established what exact dose and timing place patients at a high risk of infection. A dose of 0.3 mg/kg for at least 3 weeks is generally recognized as posing a significant risk of opportunistic infections. Nevertheless, significantly lower doses may suffice and present such a risk, too, if patients are also neutropenic or lymphopenic or are receiving other predisposing treatments.

Many fungal species, such as Mucorales, use iron as a growth factor. Some studies, mainly performed in hematological patients, have shown iron overload to be associated with an elevated risk of IFD. However, as ferritin is also an acute-phase reactant, these results are controversial.

Respiratory viral infections

Respiratory viruses, such as influenza virus, respiratory syncytial virus, adenovirus and, parainfluenza, are associated with a higher risk of IFD. Within the last, few years, this association has become more evident in patients with severe influenza requiring ICU admission and more recently, with SARS-CoV-2 (Garcia-Vidal et al., 2011; Marr et al., 2020). Respiratory viruses impair mucociliary activity and bronchoalveolar mucosa, favoring the development of IFD (Garcia-Vidal et al., 2014, 2013). Furthermore, respiratory viruses have been hypothesized as being capable of disrupting the local innate immune system and systemic host defenses.

Main groups associated with fungal infection

Hematological patients and hematopoietic stem cell transplant recipients

Patients with a hematological malignancy and those undergoing allogeneic hematopoietic stem cell transplants (HSCT) have been generally considered as facing the highest risk of developing an IFD. This series of patients are extremely susceptible to fungal infections due to the strongly toxic chemotherapies associated with profound and prolonged aplasia, and the increased survival rate in both adult and pediatric populations. However, this risk is highly dependent on factors related to underlying malignancy status and treatment, factors intrinsic to the patient and environment, and the use of prophylaxis.

Risk factors for yeast and mold infections are significantly different in general. The epidemiology of IFD in hematological patients is continuously changing, with a significant decrease in *Candida* spp. in favor of mold infections and particularly *Aspergillus* spp. (Pagano et al., 2007; Kontoyiannis et al., 2010). Tables 2 and 3 summarize the main risk factors for IFD in hematological patients and HSCT recipients, respectively.

Baseline disease and treatment-related factors in hematological malignancies and HSCT

Baseline disease is an extremely important factor when determining the risk of IFD. Patients with acute myeloid leukemia (AML) and more specifically, those receiving induction chemotherapy, have been considered as having the highest risk of developing IFD. Incidence ranging from 7% to 11% for proven/probable IFD and from 24% to 41% for possible IFD have been described in patients not receiving prophylaxis (Douglas and Slavin, 2016). However, some important factors could impact the likelihood of an IFD in these patients. Leukemias with worse prognosis, such as secondary leukemias, refractory leukemias to multiple previous lines, or those with unfavorable cytogenetics, may experience a significantly higher risk of IFD. Acute lymphoblastic leukemia (ALL) or myelodysplastic syndromes (MDS) also present high rates of fungal infections, ranging from 8% to 21% in the absence of prophylaxis. As in AML, baseline disease status, the intensity of chemotherapy regimens, and host factors can highly influence such rates. Other lymphoproliferative diseases, such as chronic lymphocytic leukemia, multiple myeloma, large B-cell lymphoma, or Hodgkin and non-Hodgkin's lymphoma have been classically considered as presenting with low risk for IFD onset. Nonetheless, an increase in incidence has been reported in the last, few years, mainly related to patients treated with multiple lines of treatment.

Table 2 Risk factors for invasive fungal disease in hematological patients.

Net state of immunosuppression
• Neutropenia: intensity, duration, and dynamics
• Lymphopenia: intensity and duration
• Cellular and humoral immunosuppression
• Malnutrition
• Advanced age
• Concomitant immunosuppressor condition
• Use of high doses of cytarabine
• Use of high doses of corticosteroids
• Use of alemtuzumab, anti-thymocyte globulin or infliximab
• Infection due to immunomodulatory virus: CMV, EBV, HHV-6, HHV-7, HHV-8
Organ and system dysfunction
• Mucosa alteration (mucositis) due to radiotherapy, chemotherapy, graft-vs-host disease, herpes viruses, etc.
• Skin and mucosa alteration due to broken barriers, secondary to graft-vs-host disease, vascular catheters, urinary catheters, chemotherapy, radiotherapy
• Renal insufficiency, hepatic insufficiency
• Obstructive and surgical events in the gastrointestinal tract
• Hyposplenias/asplenia
• Lung parenchyma insult due to viral respiratory infection
Microbial colonization and reactivation of latent infections
• Use of broad-spectrum antibiotics
• Antacid use
• Prolonged hospital stay
• Presence of foreign bodies and instrumentalization
• Ciliary function disruption
• Reactivation of latent infections: mycobacteria, toxoplasmosis, CMV, EBV, HSV, VZV, HBV, HCV
• Prior invasive fungal disease
• Increased iron deposits

Table 3 Risk factors for invasive fungal disease in hematopoietic stem-cell transplant recipients.

	<i>Invasive candidiasis</i>	<i>Mold infections</i>
Host factors	• Advanced age • Hematological malignancy • Gastrointestinal tract colonization • Multiple-site colonization prior to transplant	• Baseline disease: acute leukemia, myelodysplastic syndrome, aplastic anemia, multiple myeloma • Advanced age • State of underlying malignancy: refractory > relapsed > complete response • CMV seropositivity status (high/intermediate risk vs low risk) • Iron overload • Diabetes mellitus • Malnutrition • Prior invasive mold disease • Colonization prior to transplant
Hematopoietic stem-cell transplant treatment and complications	• Long-term central vascular catheter • Broad-spectrum antibiotic use and other infectious complications • Severe gastrointestinal mucositis due to conditioning regimen or graft-vs-host disease • High-dose total body irradiation • Prolonged neutropenia	• Type of transplant: allogenic >> autologous • Type of donor: unrelated > related • HLA relatedness: haploidentical > matched siblings > matched unrelated • Source of stem cell: cordon blood > bone marrow > peripheral blood • Conditioning regimen: full intensity > reduced intensity • T-cell depleted transplants, CD-34 selected transplants • Duration of pre-engraftment • Severe (Grade > II) graft-vs-host disease (acute or chronic) with systemic immunosuppression • Corticosteroids use • CMV reactivation (especially CMV disease) • Environmental factors: buildings, high-efficiency filters • Respiratory virus infections • Graft loss

Allogenic HSCT recipients are the other classic group of patients who face the highest risk of fungal infection. Most studies report incidence rates of IFD at around 10–15%, while other studies describe rates reaching up to 50%. Several factors influence the risk of fungal infection in these patients. Active or refractory disease at the time of the transplant is a major risk determinant. Graft source and donor relatedness impact transplant-related toxicity and risk of IFD. That stated, when compared to peripheral blood stem cells, bone marrow and umbilical cord transplants are associated with the highest risk due to delayed immune reconstitution. Similarly, haploidentical transplants and, to a lesser extent, stem cell donors who are not matched siblings are associated with longer immunosuppression and an increased risk of IFD (Marr et al., 2002; Garcia-Vidal et al., 2008). Within the post-transplant setting, graft-vs-host disease (GVHD) confers an extremely high risk of IFD on these patients due to its own immunosuppressive effect, but also due to the required immunosuppressive treatment typically with high-dose glucocorticoids (Teshima et al., 2016). CMV is also associated with an increased risk of IFD in the post-transplant setting probably due to its harming effect on innate immunity. Lastly, autologous HSCT is associated with a significantly lower risk of fungal infection due to a short duration of neutropenia and the absence of risk of GVHD.

Neutropenia is one of the main risk factors for IFD, especially in those patients with profound (<100 neutrophils/mm³) and prolonged (>7 days) neutropenia. However, several recent studies have outlined the importance and relevance of lymphopenia and lymphocyte dysfunction in IFD as well. The degree and duration of these cytopenia will impact the risk of IFD as well as the associated mortality.

Breakthrough fungal infections and patients undergoing solid organ or hematopoietic stem cell transplants after presenting with an IFD are on the rise. Such clinical scenarios pose a great challenge for treating physicians and require a multidisciplinary approach (Lionakis et al., 2018; Puerta-Alcalde et al., 2020).

Risk factors for specific fungi in hematological malignancies and HSCT

Candida spp. and other yeasts

Candida spp. continues to be the main microorganism responsible for opportunistic fungal infections within a hospital environment. Furthermore, it is the fourth leading cause of nosocomial bloodstream infections, which are associated with significant costs and attributable mortality ranging from 10% to 49%. Table 4 outlines the main risk factors and characteristics of IFD caused by *Candida* spp. and other yeasts. Patients with an increased risk of invasive candidiasis, or candidemia in its most common manifestation, are those with hematological malignancy and neutropenia who do not receive prophylaxis. Other factors typically involved in a higher risk of disseminated candidiasis are mainly iatrogenic and/or nosocomial. Chemotherapy-induced mucositis, prior *Candida* spp. colonization, antibacterial therapy (especially antibiotics with activity against anaerobes), central venous catheters, parenteral nutrition, and abdominal surgery are some of the most common risk factors. All these factors facilitate the introduction of *Candida* isolates into the bloodstream and its later dissemination, by which the CNS, eyes and heart will most likely be involved. Chronic disseminated candidiasis or hepatosplenic candidiasis occurred following neutropenia recovery; however, it is rarely seen nowadays due to the widespread use of prophylaxis.

There is great geographical variability in the distribution of species causing invasive candidiasis, according to the epidemiological characteristics and the environment, as well as the specific center. Furthermore, there are different common and specific risk factors per species involved, being associated with different rates of mortality. *Candida albicans* has commonly been the most common species to cause invasive candidiasis. Yet, the widespread use of antifungal prophylaxis within the last, few years have led to a significant increase in non-*albicans* species. This increase is challenging since these species are commonly azole resistant. In this scenario, implementing a bundle of measures have been proven to reduce mortality (Cardozo et al., 2020).

Aspergillus spp.

In the last decade, the incidence of IFD caused by filamentous fungi in hematological patients has increased. Currently, species of the genus *Aspergillus* are the main cause of invasive mold disease in such patients, causing high morbidity and mortality. *A. fumigatus* is the most frequently involved species, responsible for approximately 90% of the infections by this genus. This is mainly secondary to the relatively small size that characterizes *A. fumigatus* conidia, and which allows its penetration deep into the alveolar space. Additionally, *A. fumigatus* can grow in high temperatures (37–50 °C), being more resistant and thermotolerant than other *Aspergillus* species. Depending on geographical factors, host type or antifungal prescription, other species such as *A. flavus*, *A. nidulans* and *A. terreus* are increasingly isolated. This is important, as differences in virulence, response to treatment and prognosis of invasive aspergillosis may arise depending on the species of *Aspergillus* involved.

In relation to the host, the most frequent risk factors are profound and prolonged neutropenia, the presence of organic dysfunctions (mainly renal and hepatic) and/or an underlying pulmonary pathology that facilitates the development of invasive pulmonary aspergillosis. Risk factors associated with treatment include induction or salvage chemotherapy of acute leukemias and myelodysplastic syndromes, HSCT presenting GVHD, and prolonged and/or high-dose corticoid therapy. With respect to environmental conditions, invasive aspergillosis is of external origin (healthcare-related or extrahospitalary) in most cases, unlike most other infections that occur in a hematological patient. Hospital stay in rooms without high-efficiency filters or in close proximity to construction sites or institutional remodeling therefore increase the risk significantly.

Table 4 Risk factors and characteristics of primary *Candida* species and other yeasts that cause invasive fungal disease.

Genus/species	Frequency and characteristics	Risk factors	Mortality
<i>Candida</i> spp. (mainly <i>C. albicans</i>)	Fungemia, endocarditis, endophthalmitis, osteomyelitis, hepato-splenic candidiasis, brain abscess, meningitis, close relation to foreign bodies and endovascular devices	Abdominal surgery, central vascular catheters, total parenteral nutrition, broad-spectrum antibiotics, immunosuppressants, corticosteroids, diabetes mellitus, kidney failure, hemodialysis, transplants, pancreatitis	Overall, around 30–65%, depending on severity scores (APACHE II, SOFA), species, type of host, septic shock, etc.
<i>C. krusei</i>	2–25% of all fungemia 13% in patients with cancer 13–25% in patients with leukemia Breakthrough candidemia	Leukemia, hematopoietic stem-cell transplant, neutropenia, prophylaxis, prior use of azole	Overall 30–70%, with attributable mortality around 40%
<i>C. glabrata</i>	8–37% of candidemia 4.5–13% in patients with cancer Breakthrough candidemia	Solid tumors, abdominal surgery, central vascular catheter, advanced age, hematological malignancy, extensive burns, prophylaxis, prior use of azoles	Overall 45%
<i>C. parapsilosis</i>	12–15% of all candidemia in patients with cancer	Endovascular devices, central vascular catheters, parenteral nutrition, newborns	Overall 8%
<i>C. tropicalis</i>	4–25% of all candidemia 11–25% in HSCT 18% in hematological malignancies 4–9% in solid tumors	Acute leukemia, neutropenia, mucositis	Overall 33–90%
<i>C. lusitanae</i>	2–9% of all candidemia Breakthrough candidemia	HSCT, neutropenia, high-dose chemotherapy, hematological malignancy, prior use of polyenes	Overall mortality of 35%, with attributable mortality around 25%
<i>C. guilliermondii</i>	0.7–5.5% of all fungemia	Malignancies, HSCT, neutropenia, prior use of polyenes	Attributable mortality around 24%
<i>C. dubliniensis</i>	3–25% of oropharyngeal candidiasis in patients with HIV	Neutropenia, mucositis, oropharyngeal in HIV patients	No data
<i>Trichosporon</i> spp.	Fungemia, endocarditis, hepato-splenic forms, purple papules, chorioretinitis	Leukemia, central vascular catheter, intravenous drug user, prosthetic valves	80% in neutropenic patients
<i>Saprochaete capitata</i>	Fungemia, pneumonia, hepato-splenic forms, red skin nodules	Leukemia, central vascular catheter, prior antibiotic use, contaminated milk products	>50% in neutropenic patients
<i>Malassezia</i> spp.	Related to parenteral lipid formulations (requires lipids for growth)	Low-weight newborns, leukemia, central vascular catheter, large burns, solid organ transplant	Low, except for lung involvement
<i>Hansenula</i> spp.	Great spectrum of disease (from asymptomatic to endocarditis)	Low-weight newborns, leukemia, central vascular catheter, intravenous drug use	Low, <10%
<i>Saccharomyces</i> spp.	Fungemia, endocarditis, 0.5% of all fungemia in the ICU	Prolonged ICU stay, newborns, large burns, corticosteroid use, probiotics, central vascular catheter	Overall 30%
<i>Cryptococcus</i> spp.	Meningitis, pneumonia, fungemia, and cutaneous nodes and papules	HIV, leukemia, lymphomas, solid organ transplant, corticosteroid, cirrhosis	20–30% in patients with HIV; 30–40% in patients with malignancy

Abbreviations: HSCT, hematopoietic stem-cell transplant; HIV, human immunodeficiency virus; ICU, intensive care unit.

Emerging fungi

The last two decades have seen an increase in the frequency and severity of IFD caused by Mucorales (*Mucor* spp., *Rhizopus* spp. and *Lichtheimia* spp.), *Fusarium* spp., *Scedosporium* spp., *Lomentospora prolificans* and others. These infections have been closely related with the wide use of antifungals as both prophylaxis and treatment (Lamoth et al., 2017; Imhof et al., 2004). Although IFD by emerging fungi are rare, the importance of these types of infections lies in the aggressive behavior of the IFD, degree of host immunosuppression and broad profile of resistance to most antifungals available. All of this is associated with high morbidity and mortality rates around 65–90%.

Solid organ transplant

IFD poses a significant threat to patients undergoing a solid organ transplant (SOT). IFD caused by opportunistic fungi have a universal distribution and are mainly caused by *Candida* spp., *Aspergillus* spp. and, to a lesser extent, *Cryptococcus* spp., fungi pertaining to the order Mucorales, and other molds. IFD features vary widely depending on the organ transplanted, surgery performed, baseline disease and comorbidities, and type of immunosuppression. The most important determinants of IFD include epidemiological exposure and the net state of immunosuppression.

Table 5 Most common IFD in SOT and prophylaxis recommendations.

Transplant	Most common invasive fungal disease			Prophylaxis recommendation	Length of prophylaxis
	First	Second	Third		
Kidney	Candidiasis	Cryptococcosis	Aspergillosis	Not recommended	–
Liver	Candidiasis	Aspergillosis	Cryptococcosis	Fluconazole	1–4 weeks
				High-risk: liposomal amphotericin B or echinocandin	
Pancreas	Candidiasis	Endemic mycoses	Aspergillosis	Fluconazole	1–4 weeks
Lung	Aspergillosis	Other molds	Candidiasis	Voriconazole or nebulized amphotericin B	3–6 months
Heart	Candidiasis	Aspergillosis	Other molds	Not recommended	–
Bowel	Candidiasis	Other yeasts	Aspergillosis	Fluconazole or liposomal amphotericin B	1–4 weeks

The timing of various IFD after SOT is highly dependent on the different fungi pathogenesis. For example, within the first month of a transplant, invasive candidiasis is clearly predominant due to surgical complications. Later, secondary to the immunosuppression due to transplant or acute rejection, other IFDs become more frequent.

IFD diagnosis is challenging in SOT recipients. A nuanced approach, including the consideration of the type of transplantation, immunosuppression and time since transplant, is paramount. The role of fungal biomarkers within this setting of non-neutropenic patients is low, and the culture remains the most helpful technique. Table 5 summarizes the most common fungal diseases and prophylactic recommendations in SOT.

Risk factors for specific fungi in SOT

Candida spp. and other yeasts

Candida spp. is the main agent responsible for IFD in SOT recipients and is particularly frequent following small bowel transplants due to long-lasting abdominal surgery. In recent years, a reduction in the incidence of invasive candidiasis has been observed in patients with SOT, being reported at around 2% and in contrast to the 4–6% described in other decades. However, this incidence varies according to the organ transplanted, and is especially high in liver, pancreatic, and intestinal transplants. For these patients, invasive candidiasis implies high morbidity and mortality between 30% and 40%. In liver transplants, the main risk factors for invasive candidiasis are renal failure (especially in patients undergoing dialysis) and re-transplantation. An increase in risk has also been described in the following situations: fulminant hepatitis, need for high transfusion requirements, biliary anastomosis by Roux-en-Y technique, and need for surgical reintervention during the immediate post-transplant period. In pancreatic transplant, risk factors for invasive candidiasis include bladder drainage vs enteric drainage, graft thrombosis, the presence of pancreatic fluid fistulas in the peritoneum, cytomegalovirus infection and the age of the donor being older than the recipient. *Candida* infections can present as candidemia, peritonitis, urinary tract infection, empyema, surgical wound, or anastomosis infection.

Aspergillus spp.

The most common clinical form of invasive aspergillosis is pulmonary, with subsequent dissemination. Incidence of invasive aspergillosis varies from less than 1% in kidney and liver transplants to around 2% in pancreas and heart transplants, and 4% in lung transplants. Although invasive aspergillosis has been generally considered as a complication arising soon after the transplant, different studies have shown that incidence of such infection remains high even once this period passes. Invasive aspergillosis is particularly concentrated in specific subpopulations among SOT recipients. These high-risk patients differ according to each of the transplanted organs (Table 6). However, there are some common factors: re-transplantation, CMV disease, and hemodialysis significantly increase the risk of early invasive aspergillosis (<3 months after transplantation). For late aspergillosis (>3 months post-transplantation), risk factors include renal failure or a higher degree of immunosuppression.

In liver transplant recipients, fulminant hepatitis, and chronic graft dysfunction due to hepatitis C virus recurrence have been described as specific factors that increase the risk of invasive aspergillosis. Mortality due to invasive aspergillosis in liver transplant ranges from 50% to 65%.

Incidence of invasive aspergillosis in lung transplant is the highest among SOT recipients, ranging from 4% to 23.3% without prophylaxis. Currently, more than half of episodes occur after the first 6 months of transplantation. Airway colonization by *Aspergillus* spp. during the first 6 months after transplantation increases the risk of invasive aspergillosis by 11 times. Other factors that confer a greater risk onto this population are ischemia of the bronchial anastomosis, unilateral pulmonary transplantation, hypogammaglobulinemia, placement of a bronchial prosthesis and CMV infection. Mortality of invasive aspergillosis in lung transplant depends on clinical presentation, with those patients suffering from invasive lung disease, presenting facing a mortality rate as high as 80%.

Table 6 Risk factors for invasive aspergillosis following solid organ transplant.

	Early invasive aspergillosis	Late (>90 days after transplant) invasive aspergillosis
Hepatic transplant	Re-transplant Kidney failure, especially post-transplant hemodialysis Transplant for fulminant liver failure Complicated surgery or surgical re-operation CMV disease	Over 6 g of prednisone in the 3 months after transplant Post-transplant hemodialysis Post-transplant kidney failure Post-transplant leukopenia ($<500/\text{mm}^3$) Chronic graft failure due to hepatitis C virus recurrence
Lung transplant	Bronchial Anastomosis Ischemia or bronchial stent placement CMV Infection Acute rejection Single-pulmonary transplant Colonization by <i>Aspergillus</i> spp. pre-transplant or within the first year Hypogammaglobulinemia (IgG <400 mg/dL) CMV disease	Unilateral pulmonary transplantation Chronic rejection
Heart transplant	Isolation of <i>Aspergillus</i> spp. in respiratory tract cultures Surgical re-intervention CMV disease Post-transplant hemodialysis CMV disease	ICU re-admission Post-transplant kidney failure Levels FK > 15 or CyA > 500 after month 3 > 2 episodes of acute rejection
Renal transplant	Graft loss Hemodialysis High and prolonged doses of steroids CMV disease	—

Abbreviations: CMV, cytomegalovirus; ICU, intensive care unit; FK, tacrolimus; CyA, cyclosporine A.

Cryptococcus spp.

The incidence of cryptococcosis in the American TRANSNET cohort accounted for 8% of all IFD, being the third most frequent causal agent after candidiasis and invasive aspergillosis, and is particularly frequent among kidney and heart recipients (Pappas et al., 2010). Evidence suggests that most cryptococcoses in SOT recipients result from reactivation of subclinical infection and cause infections with late clinical presentation (over 12–24 months after transplant). Patients receiving high doses of corticosteroids or monoclonal antibodies, such as alemtuzumab and infliximab, appear to face the highest risk of disseminated cryptococcosis.

Emerging fungi

Over the last, few years, mucormycosis has been reported as increasingly important in SOT, occurring late after transplant in general (Park et al., 2011). The most common clinical presentation forms are fungal pneumonia and rhinosinus infection. A high degree of clinical suspicion is necessary, as a delayed initiation in administering appropriate therapy is associated with poor prognosis (Chamilos et al., 2008). However, the frequent lack of profound neutropenia results in a more favorable prognosis for these patients when compared to hematological patients, with mortality rates around 20%. Classical risk factors for invasive mucormycosis are uncontrolled diabetes mellitus, corticosteroids, neutropenia, renal failure, reactivation of herpes viruses, malnutrition, and prior use of either voriconazole or caspofungin (Singh et al., 2009).

Critical patients

In the last decades, intensive care units have grown in complexity for various reasons: admission of older and more comorbid patients, rising admission of immunosuppressed patients, increased survival in situations of extreme frailty, advancement and novelty of surgical techniques, and multiple instrumentations. As a result, incidence of IFD has risen in critically ill patients, with patients admitted to intensive care units constituting the second group in frequency of invasive mycosis (40%) only after surgical patients. This is of the utmost importance since the impact of IFD on the prognosis of these patients is huge. Table 7 shows the main risk factors for IFD in ICU patients.

Invasive candidiasis is the most frequent fungal infection in this setting, followed less commonly by invasive aspergillosis. The percentage of fungal isolates in severe infections depends on patient characteristics, patient's individual risk factors, and the type of ICU. In a general ICU, approximately 15–20% of severe infections are IFD.

There are three fundamental factors in managing fungal infections in critically ill patients: (i) those related to the host, such as the presence of comorbidities or clinical severity; (ii) those related to the pathogen, such as antifungal sensitivity or fungal virulence; (iii) those related to treatment, such as the spectrum of activity, PK/PD characteristics, safety and interactions.

Table 7 Risk factors for invasive fungal disease in intensive care unit patients.

Non-neutropenic	Neutropenic
• Disease severity • Major surgery (mainly abdominal) • Central venous catheters • Prior use of antibiotics • Total parenteral nutrition • Renal or hepatic insufficiency • Extreme ages (old patients and low-weight newborns) • Corticosteroid use • Multifocal colonization • Need for mechanical ventilation • Comorbidities • Cellular immunity dysfunction due to severe inflammatory response syndrome	• Baseline disease • Solid organ transplant and hematopoietic stem cell transplant • Prior use of antibiotics • Hemodialysis • Need for mechanical ventilation • Chemotherapy and other immunosuppressants • Pancreatitis • Disease severity

Risk factors for specific fungi in critical care units

Candida spp.

Candida spp. is the fungal genus that most frequently causes IFD in critical care patients. Incidence of invasive candidiasis is 10 times higher in critical patients than when compared to patients in general wards from the same hospital. *Candida albicans* is the fifth most frequent pathogen isolated as a cause of major intra-ICU infections. *Candida* spp. is the second leading cause of urinary tract infection, and *C. albicans* the second causal pathogen, only after *Escherichia coli*. In several series, different species of *Candida* spp. constitute the third or fourth most frequent cause of bloodstream infection (Kett et al., 2011). Around 10% of these infections are candidemia, with *C. albicans* being the fourth etiological agent globally (Wisplinghoff et al., 2004).

In ICU patients, overall mortality stands at approximately 45–70% with an attributable mortality of 25–45%. The following factors are associated with increased mortality in critically ill patients with invasive candidiasis: (i) the type of *Candida* species involved, as some species have a higher degree of virulence; (ii) inappropriate antifungal treatment; (iii) delay in starting appropriate antifungal treatment; (iv) degree of involvement, as measured by the APACHE scale; (v) prolonged ICU stay; (vi) secondary renal failure; (vii) hematological malignancies; (viii) need for mechanical ventilation; (ix) need for vasoactive support.

Although almost 80% of ICU patients can be colonized by *Candida* spp., only around 10% of these patients will present with invasive candidiasis. Critical patients with a higher risk of invasive candidiasis are generally those with a history of major intestinal surgery, especially those on total parenteral nutrition, receiving broad-spectrum antibiotics, with central venous catheters, with any type of immunosuppression, on dialysis or in the most severe condition.

Identifying risk factors early for invasive candidiasis is fundamental in order to initiate prompt treatment and thereby reduce the mortality rate associated with such infections. There are different rules to identify patients at risk of invasive candidiasis. One of the most recognized rules is the “*Candida* score” (León et al., 2006). This score allows for the identification of critical, non-neutropenic patients with suspected candidemia. It is based on the predictive value of different risk factors previously demonstrated by logistic regression. Estimated scores obtained for each risk factor are as follows: parenteral nutrition—1, previous surgery—1, multifocal colonization by *Candida*—1, and severe sepsis—2. A value of a “*Candida* score” equal or higher than three allows clinicians to select those patients who may benefit from early antifungal treatment under the clinical suspicion of invasive candidiasis, with a sensitivity of 81% and a specificity of 74%. This score has been prospectively validated, demonstrating that <5% of patients with a “*Candida* score” below three developed invasive candidiasis (Leroy et al., 2011). Conversely, of patients with a score higher than 3, 30% presented with invasive candidiasis. These scores may therefore be useful during the decision-making process about whether empirical treatment should be initiated in a febrile patient. Similarly, these scores may even help to assess the use of antifungal prophylaxis in patients who have high score values.

Aspergillus spp.

In recent years, an increase in the incidence of invasive aspergillosis in critical patients without a diagnosis of neutropenia or a hematological disease has been documented. Such incidence ranges from 0.3% to 5.8% with overall mortality close to 80% and attributed mortality of 20%. *Aspergillus fumigatus* is the main species involved, followed by *A. niger* and *A. flavus*.

Critically ill patients present with an alteration in the immune response and depression of the phagocytic mononuclear system function, occurring in late-phase multiorgan dysfunction, primarily. Such immunosuppression especially affects alveolar macrophages and can explain the increased risk of pulmonary aspergillosis. Predominant risk factors for invasive aspergillosis in the ICU are chronic obstructive pulmonary disease (COPD) and steroid treatment. Chronic liver disease, malnutrition and diabetes mellitus are also considered risk factors.

Association of severe influenza viruses, especially influenza A (H1N1), with invasive aspergillosis has been recently described. One hypothesis for such association is that influenza infection may cause diffuse injury to the respiratory mucosa and facilitate

fungus invasion. A recent review on this topic showed that the great majority of invasive aspergillosis cases were caused by influenza A (only 10% of cases were described as being caused by influenza B) and median time from influenza to invasive aspergillosis was only 5 days (interquartile range 2–11 days) (Schauwvlieghe et al., 2018). Twenty-eight percent of cases had no comorbidity and only 25% had immunosuppression. Furthermore, 21-day mortality was 57%. Most importantly, performing a diagnosis of such pathogenic entity remains challenging, as around 50% of cases did not meet classical criteria for invasive aspergillosis, 65% presented with atypical CT lesions and galactomannan was positive in less than a third of all cases.

The coronavirus disease 2019 (COVID-19) pandemic has become a great health challenge, with tremendous impact on our social, economic and health livelihoods. Aspergillosis complicating COVID-19 has been sporadically reported since the beginning of this devastating pandemic; however, exact incidence of this severe complication is unknown and commonly underreported (Marr et al., 2020). Most importantly, most patients who experience this complication do not present any of the classic risk factors, e.g., immunosuppression or neutropenia, even though corticosteroid use is common in the different series (Apostolopoulou et al., 2020). Patients with a higher risk are those requiring ICU admission and mechanical ventilation due to moderate to severe to acute respiratory distress syndrome (ARDS) (Dupont et al., 2020).

Other fungal infections

Other types of yeasts, such as *Cryptococcus*, *Rhodotorula* or *Trichosporon*, are seldomly reported in the ICU context. Like *Candida* spp., these types of yeast are mainly related to surgical procedures and long-term central vascular catheters. Similarly, invasive mold disease caused by either Mucorales, *Fusarium* spp. or *Scedosporium* spp. is very rare in this group of patients.

Pediatric patients

The burden of pediatric patients at risk of IFD has also been on a rise in the last, few years. Fungal infections in this population are associated with significant morbidity and mortality. Characteristics and clinical manifestations of pediatric patients are different from those observed in adults. Table 8 shows the main risk factors for IFD in pediatric patients. In order to assess the risks of these patients, the following items should be borne in mind: (i) etiological agents involved may be different from those seen in the adult population; (ii) there is a greater frequency of focal infection in pediatric patients following a fungemia, even though clinical findings and manifestations may be unspecific; (iii) the sensitivity and specificity of available diagnostic resources are lower and there is less evidence to apply early treatment; (iv) the use of antifungals in pediatrics is very limited due to the both lack of studies on pharmacokinetics and toxicity in this population and challenges presented in monitoring such patients; (v) with the exception of the neonatal population, few studies consider the risk by age group.

The most common risk factors in this population are the following: (i) extremely premature infants (particularly those with a weight <1500 g); (ii) children with cancer; (iii) those undergoing HSCT or SOT; (iv) neutropenic children; (v) those with long ICU stay; (vi) children undergoing invasive procedures and major surgeries; (vii) children with primary or acquired immunodeficiency, congenital cardiopathies or pulmonary diseases.

Table 8 Special-risk populations and risk factors for invasive fungal disease in the pediatric population.

Pediatric populations at high risk of invasive fungal disease
• Immunosuppressed patients
• Newborns, especially those with low birthweight (<1500 g)
• Patients admitted to the ICU
• Onco-hematological patients and HSCT recipients
• Solid organ transplant recipients
• Children infected with HIV
• Congenital immunodeficiencies
Main risk factors for invasive fungal disease (mainly <i>Candida</i> spp.)
• Age: newborns and breastfeeding babies (microbiota and local immunity have not sufficiently developed)
• Use of corticosteroids: due to immunity alteration
• Broad-spectrum antibiotics: due to alterations in bacterial microbiota
• Skin and mucosa alteration: vascular catheters, urinary catheters, peritoneal catheter, valvular prosthesis or any other foreign device
• Malnutrition and immunosuppression: hypovitaminosis, hypogammaglobulinemia, cellular immunity dysfunction
• Total parenteral nutrition
• Prior abdominal surgery
• Respiratory viral infections
• Mechanical ventilation
• <i>Candida</i> spp. multiple-site colonization

Abbreviations: ICU, intensive care unit; HSCT, hematopoietic stem-cell transplant; HIV, human immunodeficiency virus.

***Candida* spp. and other types of yeast in pediatric patients**

Candida spp. is the main agent responsible for IFD in the pediatric patient. In this population, most cases of invasive candidiasis are produced by *C. albicans*. However, given the increasing use of azoles in recent years, an increase in other species with decreased sensitivity to azoles, such as *C. glabrata* or *C. krusei*, has been observed.

There are certain risk factors that predispose the pediatric population to invasive candidiasis:

- 1) Skin colonization: 5–10% of newborns admitted to the ICU are colonized by *Candida* spp. In low-birth-weight infants, the percentage seems to be slightly higher. At 1 week of admission, colonization increases to 50%; at 1 month, it is 64%.
- 2) Broad-spectrum antibiotic therapy over a 5-day period: associated with the destruction of intestinal bacterial flora and colonization by *Candida* spp. with subsequent invasion of the mucosa.
- 3) The presence of a central venous catheter: especially in critical and immunosuppressed children, or pediatric patients undergoing chemotherapy, transplants, or with parenteral nutrition, etc. Some species, such as *Candida parapsilosis* and *Candida tropicalis*, can produce biofilms making it difficult to eliminate them effectively.
- 4) Hyperglycemia: this can favor fungal growth and decrease the host's defense ability by altering the regulation of protein adhesion genes and the capacity of the complement to opsonization.
- 5) The loss of protective barriers: this may include damage to skin barriers caused by wounds or burns and a decrease in gastric acidity due to the use of proton pump inhibitors. The latter can favor fungal growth in the gastrointestinal tract.
- 6) Other factors that directly alter a patient's defense mechanisms: mechanical ventilation, major abdominal surgery, acute pancreatitis, diabetes mellitus, corticosteroid therapy, neutropenia, neutrophilic dysfunction and other immunological changes.

In premature infants, especially those who weigh little (1000–1500 g), invasive candidiasis associated risk factors include those previously mentioned, with emphasis on malnutrition and invasive devices. In preterm infants, the main risk factor associated with invasive candidiasis is an immature immune system, especially with respect to low levels of maternally transmitted immunoglobulin G, decreased opsonization and decreased complement functions. In older pediatric patients, risk factors resemble more closely those found in adults.

IFD caused by emergent yeasts, such as *Cryptococcus* or *Trichosporon*, are seldom and generally affect immunosuppressed children secondary to HIV, SOT, HSCT, primary immunodeficiencies or hematological malignancies.

***Aspergillus* spp. and other molds in pediatric patients**

Incidence of invasive aspergillosis and other molds in pediatric patients has increased in the last decades. Around 75% of all mold infections in pediatric patients are observed in those with onco-hematological conditions. In such populations, cumulative incidences are described at being around 2%, with related mortality at 55%. Other populations at risk of invasive mold disease are SOT recipients and patients with primary or acquired immunodeficiency. These infections are also seen in critical care patients, especially in premature infants with a low birth weight.

Similar to adults, profound and prolonged neutropenia (<500 neutrophils/mm³ and >10 days) is the main risk factor for invasive mold disease in these populations. Some other factors are the following: (i) prior chemotherapy; (ii) broad-spectrum antibiotics; (iii) high-dose corticosteroids; and (iv) some specific immunosuppressants, such as purine analogs, monoclonal antibodies, cyclosporine, or tacrolimus.

Epidemiology and clinical profiles of patients with invasive mold disease other than *Aspergillus* spp., such as mucormycosis or hyalohyphomycosis, are less well characterized in pediatric patients.

Solid tumor patients

In the last years, the number and mechanisms of oncological treatments have increased. For many of these treatments it is still too early to know if they will be related to a significantly heightened risk of IFD. Some of these treatments, such as tumor necrosis factor inhibitors, anti-lymphocyte antibodies, interleukin inhibitors, tyrosine kinase inhibitors or immune checkpoint inhibitors have been reported to be associated with cases of fungal diseases (Davis et al., 2020). However, attributing the specific role of these agents in the likelihood of fungal infections is challenging, as this series of patients often receive multiple lines of therapies, present with advanced malignancies and commonly receive other immunosuppressive agents, such as corticosteroids. Finally, toxicities secondary to these agents usually require high doses of corticosteroids, being the final cause of infection in many cases.

***Candida* spp. and other yeast in oncological patients**

While candidemia in patients with hematological malignancies is mainly related to profound and prolonged neutropenia and to important mucositis, these factors are rather uncommon in patients with solid tumors. The main risk factors for yeast infection (mainly *Candida* spp.) in solid tumors are oncological surgery and concomitant complications, especially abdominal surgery; ICU admission and need for mechanical ventilation; parenteral nutrition and the frequent need for long-term central vascular catheters. As fluconazole is not systematically used in these patients (in contrast to hematological patients), the prevalence of non-*albicans* species of *Candida* and other yeasts (such as *Trichosporon* spp.) is expected to be lower.

***Aspergillus* spp. and other molds in oncological patients**

The diagnosis of invasive aspergillosis is commonly not considered in oncological patients, leading to significant delays in proper diagnosis and treatment, as well as worse outcomes more frequently. The aforementioned EORTC/MSG definitions for fungal infections are focused on hematological patients (De Pauw et al., 2008). Oncological patients do not usually meet host criteria and radiological signs of pulmonary fungal disease can vary significantly in these individuals. Similarly, the yield of fungal biomarkers, such as galactomannan, has not been well established in these patients. Despite these difficulties, IFD and predominantly invasive pulmonary aspergillosis, are being increasingly reported in patients with solid tumors, with mortality rates similar to those observed in hematological patients. Main risk factors associated with invasive pulmonary aspergillosis in patients with solid tumors are primary pulmonary compromise due to neoplasia, use of glucocorticoids, prior chemotherapy, prior radiotherapy, critical illness and previous pulmonary disease, such as chronic obstructive pulmonary disease or asthma (Dib et al., 2020). Additionally, mold disease in oncological patients can commonly present in more saprophytic or chronic forms in lung areas previously affected by baseline disease or treatment, such as cavitation, scars, or bronchiectasis.

***Pneumocystis jirovecii* and others**

The emergence of new-generation immunosuppressive agents like rituximab and other cytotoxic agents have been associated with an increased number of *Pneumocystis jirovecii* pneumonia (PJP) cases in patients with solid tumors. Apart from the direct immunosuppressive effect of these agents, toxicity requiring glucocorticoids is the main factor evidenced in many cases. Profound and prolonged lymphopenia predisposing to PJP can also develop after biological and immunomodulatory treatments. Although primary prophylaxis with cotrimoxazole could help diminish the risk of PJP, its value in patients without HIV has barely been tested, and clear indications for treatment initiation are lacking. Similarly, the value of corticosteroids in these patients is less proven, although it seems to be beneficial (Mundo et al., 2020).

Most importantly, the mortality of patients without HIV and with PJP seems to be higher than in patients with HIV (Avino et al., 2016). Several reasons may explain this fact: (i) less awareness of this disease among oncologists, leading to delays in diagnosis and treatment; (ii) difficulties in differentiating pulmonary involvement in PJP from that secondary to lung toxicity secondary to cancer treatments, or from radiotherapy pneumonitis; (iii) patients with oncological diseases and clinical suspicion of PJP frequently present with an advanced tumor state and thereby limit the possibility of performing a bronchoscopy and obtaining a firm diagnosis.

Sporadic case reports exist of different rare fungal infections, such as cryptococcosis in patients with solid tumors. However, these cases are highly uncommon and usually due to a sum of factors, such as multiple lines of therapy for a progressive disease, corticosteroids, and ICU admission.

Other groups of at-risk patients

Patients with HIV

Patients infected with HIV have been the paradigm of the immunosuppressed patient for a long time. In fact, for reasons unbeknownst, patients with low CD4 present with higher rates of certain IFD (oropharyngeal candidiasis, meningeal cryptococcosis, etc.) than, for example, hematological patients with similar lymphocyte counts. However, since the development of highly active antiretroviral therapy (HAART), frequency and severity of IFD have been widely improved. In the beginning years of the HIV pandemic, rates of fungal infection were reported at around 25%, but rapidly decreased after the introduction of HAART (Antinori et al., 2009). Alongside HAART, better knowledge of such infections and improved therapies have resulted in a significant decline in morbidity and mortality. However, in low-income countries, IFD continues to be a huge problem for patients with HIV/AIDS, particularly cryptococcosis and histoplasmosis. Over 200,000 new cases of cryptococcal meningitis occur each year worldwide, resulting in 181,000 deaths; the majority of which occur in sub-Saharan Africa (Rajasingham et al., 2017). In Latin America, histoplasmosis is one of the most common opportunistic infections in patients with HIV, with rates of mortality around 30%.

When evaluating IFD in patients with HIV, environmental, structural, and immunological factors should be considered. One of the main risk factors in this population is a CD4 count below 200/mm³. Risk factors for developing IFD depends mainly on the following aspects: (i) degree of cellular immunity impairment; (ii) use of antifungal therapy; (iii) risk of environmental exposure; (iv) neutropenia; (v) use of prophylactic regimens.

Pneumocystis jirovecii pneumonia or PJP is the most common invasive fungal disease in patients with AIDS and is also the most common opportunistic respiratory infection in this population. It typically occurs in patients with HIV and a CD4 count <200 cells/mm³ who are not receiving appropriate prophylaxis. Depending on the geographical context and degree of immunosuppression, the other, more frequently seen IFD in patients with HIV are invasive aspergillosis and cryptococcosis. Almost all cases of cryptococcal-disseminated disease (mainly with meningitis +/- encephalitis) are seen among patients with AIDS and a CD4 count <100 cells/mm³.

In some high-income countries with high adherence of patients to HAART, the incidence of both pneumocystosis and cryptococcosis has sharply decreased. In some such areas, these IFD have been replaced by endemic fungi, such as *Histoplasma* spp. and *Coccidioides* spp., or endogenous IFD, such as invasive candidiasis.

Chronic pneumopathy patients

Pulmonary aspergillosis is the most common fungal disease in patients with chronic pneumopathy (mainly chronic obstructive pulmonary disease [COPD]), causing different entities, such as invasive aspergillosis, chronic pulmonary aspergillosis (including aspergilloma), hypersensitivity pneumonitis, and allergic bronchopulmonary aspergillosis. Invasive pulmonary aspergillosis in patients with COPD is an extremely severe entity, with a high mortality rate of around 90% (Bulpa et al., 2020). A relevant factor for this poor prognosis seems to be the difficulties in diagnosis, arising from a non-specific clinical presentation and the absence of complementary, non-invasive tests. In addition, as these patients are commonly considered as non-immunosuppressed, diagnosis may be further delayed due to the lack of awareness regarding diagnostic possibility of invasive pulmonary aspergillosis. Further, the absence of an agreed definition and infection surveillance measures, as well as the challenge in differentiating colonization from infection add further obstacles.

The main factors associated with an increased risk of invasive aspergillosis are the administration of corticosteroids (mainly systemic but also inhaled), advanced stages of the disease (Gold III-IV), administration of broad-spectrum antibiotics in the previous months, and ICU admission, especially.

Epidemiology

Candidiasis is a cosmopolitan fungal infection caused by fungi of the genus *Candida*. These yeasts exist in single-cell form and multiply by budding. In human samples, *Candida* spp. is observed as round yeasts 4–6 μ m in diameter with a thin wall, which can emit pseudo-hyphae, particularly *C. albicans*. *Candida* spp. is saprophyte of skin, vagina and intestinal flora, and is found in 30% of individuals (Sardi et al., 2013). The majority of disseminated diseases is of endogenous origin with digestive, skin, or genitourinary portal of entry. Exogenous transmission is rare, generally secondary to human-to-human transmission by manual, oral, or sexual, or vertical route during the perinatal period.

Ten main species are pathogenic to humans, more than 90% of invasive candidiasis being attributed to five species: *C. albicans*, *C. glabrata*, *C. parapsilosis*, *C. tropicalis*, and *C. krusei* (Falagas et al., 2010; Guinea, 2014; Pfaller et al., 2005). *C. albicans* is the most widespread and ubiquitous yeast. Until the 1990s, it was responsible for about two-third of candidiasis with a decreasing incidence in time (Guinea, 2014). Increased use of antifungal prophylaxis, and other factors such as age, use of broad spectrum antibiotics, increased life expectancy with cancer have substantially changed the epidemiology over the past two decades (Farmakiotis et al., 2014; Guinea, 2014; Leroy et al., 2009; Tan et al., 2015). Species with lower susceptibility to antifungals have emerged. These strains are associated with intrinsic resistance (*C. krusei*) or reduced susceptibility to azoles (*C. glabrata*) or echinocandins (*C. parapsilosis*). Epidemiological changes are largely linked to the use of antifungal drugs, particularly azoles. Geographic location and age of the patient are two factors influencing the distribution of species. *C. glabrata* infections are more particularly present in the northern hemisphere, northern Europe, the United States, and Canada, and their frequency increase with age and number of cancer patients previously exposed to antifungal treatments (Farmakiotis et al., 2014; Milazzo et al., 2014). In contrast, *C. parapsilosis* infections are more common in the southern hemisphere, especially Asia, and in southern Europe. They typically affect newborns and patients with intravenous catheters (Arnold et al., 2010; Gamaletsou et al., 2012; Pappas et al., 2018). *Candida tropicalis* is more common in patients with leukemia and neutropenia (Silva et al., 2012). Common risk factors for *Candida* infections are age, colonization, length of stay in intensive care, broad spectrum antibiotic therapy, intravascular devices, diabetes, parenteral nutrition, renal failure, hemodialysis and hemofiltration, antifungal prophylaxis, surgery, acute necrotizing pancreatitis and corticosteroid therapy.

A new *Candida* species has emerged and is currently present in all continents. *Candida auris* was first described in 2009 in Japanese and Korean patients. Prevalence and mortality are largely underestimated due to its being a difficult-to-identify species (Navalkele et al., 2017). In a prospective study conducted in intensive care in India, *C. auris* was the fifth cause of candidemia, with a prevalence of 5.3% (Rudramurthy et al., 2017). Analysis was even more worrisome in South America, between March 2012 and July 2013, where *C. auris* represented the sixth pathogen found in blood stream infections.

The risk factors for *C. auris* infection seemed quite similar to those of other *Candida* spp. A study comparing patients with *C. auris* candidiasis versus those with candidemia from another *Candida* spp. showed that patients with respiratory disease, vascular surgery, and 30-day exposure to antifungal drugs were at high risk of developing an infection with this new (Rudramurthy et al., 2017). Regarding resistance to usual antifungal treatments, more than 60–80% of *C. auris* isolates are resistant to fluconazole, 10–30% to amphotericin B, and approximately 10% are resistant to echinocandins (Chakrabarti et al., 2015; Chowdhary et al., 2013; Colombo et al., 2014).

The worldwide incidence of candidemia is difficult to ascertain. It depends on hospital admissions or ICU admissions, rate of cancer, rate of transplant recipients, patient age, and the overall health of the population. In the United States from 2008 to 2011, candidemia had an annual incidence rate of 13.3–26.2/100,000 population associated with a 30-day mortality rate of 28–29% (Cleveland et al., 2012; Fagan et al., 2013). Candidemia is the fourth most common cause of death and represents more than 85% of all fungemia (Sardi et al., 2013; Silva et al., 2012). To compare, in France from 2001 to 2010, the annual incidence rate was 3.6/100,000 population (Bitar et al., 2014). In the US, candidemia represents 10% of blood stream infections versus 2–3% in Europe (Asmundsdottir et al., 2013; Cleveland et al., 2012, 2015; Meyer et al., 2013; Pfaller and Diekema, 2007; Puig-Asensio et al., 2014).

A large prospective population-based cohort study carried out between May 2010 and April 2011 in 29 Spanish hospitals described the epidemiology of candidemia according to main comorbidities (Cuervo et al., 2015). In older patients >75 years, a urinary origin of candidemia was more often found; risk factors such as presence of central venous catheter, parenteral nutrition, neutropenia, immunosuppressive therapy were less often encountered. In neutropenic patients, candidemia was less often linked to long-term catheter infection and was more frequently caused by *C. tropicalis*, *C. krusei*, and *C. glabrata*. 30-Day mortality was the same as in the general population, with a rate approximating 30%. In surgical wards, mortality attributable to candidemia was significantly lower than in medical wards, hematology or ICU. This may be due to less severe underlying diseases. In solid organ transplant recipients, a high rate of species resistant to fluconazole (>50%) and non-albicans species, particularly *C. glabrata*, has been described. In this setting, early catheter withdrawal and early initiation of appropriate antifungal therapy were protective with regard to 30-day mortality (Fernández-Ruiz et al., 2019; Fortún and Gioia, 2017; Ramos-Martínez et al., 2017; Vena et al., 2017).

Invasive candidiasis, accounting for 70–90% of all invasive fungal diseases, remains the most common cause of sepsis or septic shock of fungal origin. Invasive candidiasis is associated with high mortality, particularly in ICUs, even though this rate has varied among studies from 5% to 71%. Factors such as *Candida* species, age, underlying chronic diseases and hospitalization in ICUs influence the mortality rate (36–40). It should be noted that the candidiasis increase in ICU has been reported worldwide (Colombo et al., 2014; Lortholary et al., 2014). When compared with candidemia outside of ICUs, ICU candidemia is characterized by higher pre-exposure to azoles and echinocandins, a lower incidence of *C. parapsilosis*, and higher mortality (Leroy et al., 2009; Lortholary et al., 2014). In patients with hematological malignancies, the incidence of invasive candidiasis has decreased with the use of antifungal prophylaxis (Gamaletsou et al., 2014; Sipsas et al., 2009). Studies have shown that the proportion of *C. krusei* and *C. glabrata* is higher in this population, probably due to prolonged exposure to azoles (Bodey et al., 2002; Cleveland et al., 2015; Hachem et al., 2008; Horn et al., 2009; Lockhart et al., 2011; Schuster et al., 2013).

In the general population, attributable mortality is mainly due to delayed administration of an appropriate antifungal treatment (Arnold et al., 2010; Pfaller and Diekema, 2007; Puig-Asensio et al., 2014).

Despite improvement in antifungal treatments, the associated mortality has remained unchanged for 10 years, posing a considerable public health problem. Invasive candidiasis is responsible for a high cost of health care due mainly to prolonged hospitalization, especially in ICUs, and to protracted courses of expensive antifungal treatments. Several sources estimate the total median cost per person to be more than US \$ 50,000 (Asmundsdottir et al., 2013; Craver et al., 2010; Lortholary et al., 2014; Moran et al., 2009, 2010; Pfaller and Castanheira, 2016; Pfaller and Diekema, 2007).

Definition

Candidiasis brings together three distinct entities: asymptomatic colonization of a non-sterile site, i.e., skin, digestive and respiratory tracts; superficial skin and mucosal infections; and invasive tissue infections. The European Organization for Research and Treatment of Cancer (EORTC) and Treatment of Cancer and the Mycoses Study Group Education and Research Consortium reviewed and updated the criteria for invasive disease diagnosis in 2019 (Ascioglu et al., 2002; Donnelly et al., 2019):

- proven: For all patients, regardless of their immunological status, histopathologic, cytopathologic, or direct microscopic examination of a specimen obtained by needle aspiration or biopsy from a normally sterile site (other than mucous membranes) showing *Candida*; recovery of *Candida* spp. by culture of a sample obtained by a sterile procedure from a normally sterile site; blood cultures growing *Candida* spp.
- probable: The patient must meet at least one criterion from each of these categories: risk factors intrinsic to the host (recent neutropenia, hematologic malignancy, allogeneic stem cell transplantation, prolonged corticosteroid therapy, recognized T-cell immunosuppressants, inherited severe immunodeficiency, acute graft-versus-host disease), clinical criteria and mycological criteria (two consecutive positive β -D-glucan or positive T2Candida);
- possible: Presence of host risk factor and clinical criteria but no mycological evidence.

Physiopathology

Candida spp. becomes pathogenic only when the host microbiota or antifungal immune defenses (phagocytes, T lymphocytes) are disturbed. Antibiotics, especially broad spectrum antibiotics active on anaerobes, consequently permit growth of yeasts by modifying digestive or vaginal microbiota. The integrity of the mucocutaneous barrier can be affected by surgical wounds, chemo- or radiation-induced mucositis, or central venous catheters. Once the barrier is altered, the yeasts pass into the bloodstream. Skin and mucosal damage occurs mainly in patients with an acquired immune deficiency, as shown by their high prevalence in patients with HIV infection. However, deep-seated *Candida* infections are often linked to a deficit in innate immunity or to an impairment of phagocytic functions (Sardi et al., 2013).

Candida spp. has several virulence factors: membrane and cell wall barriers, dimorphism, proteins related to stress tolerance, hydrolytic enzymes and toxin production. *Candida* is able to form biofilm, an extracellular matrix secreted by different bacteria and yeasts. It allows host colonization, adhesion to foreign materials (catheters, prostheses, etc.), and protection against antifungal treatments.

Surface receptors on innate immunity cells recognize the conserved structures of *Candida*, essentially components of the yeast wall, such as chitin, β -glucans, or mannans. This recognition leads to an inflammatory reaction characterized by macrophage activation and neutrophil influx. After which, Th1/Th17 immune response is initiated, allowing the production of cytokines such as gamma interferon and interleukins 17 and 19.

In chronic disseminated candidiasis (CDC), deregulation of the Th1 immune response explains the pathophysiology of CDC. Chemotherapy-induced neutropenia allows establishment of an anti-inflammatory environment with a dominant Th2/Treg response. Neutropenia combined with inflammation of the mucous membranes and ulcers along the digestive tract promoted by chemotherapy facilitates *Candida* translocation in the portal venous system through liver and spleen. After neutrophil recovery, specific anti-*Candida* immunity characterized by a pro-inflammatory Th1 response is restored promoting the occurrence of clinical and radiological symptoms. The pro-inflammatory response can quickly become excessive with an imbalance in the Th1-Th2/Treg immunological balance leading to an inflammatory immune reconstitution syndrome (IRIS) (Candon et al., 2020; Dellièrre et al., 2018).

General information on diagnostic methods

Direct examination and culture: The gold standard methods

The diagnosis of certainty for *Candida* infection is based on yeast isolation from blood or pathological products (tissues or urine). Despite relatively low sensitivity of around 21–71%, blood cultures remain an essential diagnostic tool (Clancy and Nguyen, 2013). Their sensitivity varies according to species, culture media, and underlying comorbidity. It is lower in neutropenic patients and in those receiving prophylactic antifungal therapy (Jordana-Lluch et al., 2014; Neely et al., 2013). Blood cultures should be taken daily from different sites. Growth times vary from one *Candida* species to another (1–14 days). For instance, *C. tropicalis* grow in an average of 19 h compared to 75 h for *C. glabrata*. Incubation time is approximately 5 days, to which approximately 24–48 h for species identification must be added. A negative culture does not rule out *Candida* infection. However, due to its high specificity, a yeast in a blood culture is very likely to be *Candida*, other yeasts such as *Cryptococcus* spp. being rare (Griffin and Hanson, 2014; Pappas et al., 2018).

Since *Candida* is a saprophyte of skin and mucous membranes, interpretation of unprotected samples (throat sample, endoscopic sample, skin biopsy, stool and urine samples, sputum ...) must be carried out with care. Their positivity is most often linked to colonization, which is nevertheless important to identify in patients at risk of invasive infection. On the other hand, the presence of *Candida* in bronchoalveolar lavage almost always signals colonization.

In addition, the gold standard for diagnosing deep-seated candidiasis without associated candidemia is fungal culture in normally sterile tissues or biological fluids. As with blood cultures, sensitivity is lacking. Moreover, it is often difficult to perform deep-seated biopsies due to fragile population, which complicates the performance of invasive procedures (Clancy and Nguyen, 2013, 2018; Pappas et al., 2018).

Indirect diagnostic tools

1,3- β -D-Glucans

1,3- β -D-Glucans (BDG) are sugar components of the cell wall of most fungal species. The positivity of the BDG assay is therefore not specific to invasive candidiasis. There are currently four commercial kits (fungitell[®], fingitec-G[®], Wako[®], and Maruha[®]) with similar performances. The Fungitell[®] assay was approved by the United States Food and Drug Administration in 2004 to improve the sensitivity of invasive candidiasis diagnosis and is the most widely used test in the world.

For diagnosis of an invasive fungal disease, the European Society of Clinical Microbiology and Infection Diseases (ESCMID) guidelines recommend repeating the sample: two consecutive positive samples have very high specificity (96–98%), good positive predictive value (79–83%), and good negative predictive value (91–94%). Due to low sensitivity (49–63%), this test should be combined with clinical, radiological, and microbiological proofs.

There are several limitations to the use of BDG. It does not distinguish an invasive fungal infection by *Candida* spp. from another fungus (Pfaller and Castanheira, 2016). There are false positives, especially with previous administration of albumin or immunoglobulins, during hemodialysis, and during some systemic bacterial infections or severe mucositis. Administration of antibiotics such as intravenous amoxicillin-clavulanic acid or piperacillin-tazobactam is less and less an issue. The test is also better for patients without hematological malignancy. While it is recommended to perform it twice a week when an invasive infection is suspected in at-risk patients, it has not yet been validated for children (Clancy and Nguyen, 2013; Karageorgopoulos et al., 2011; Lamoth et al., 2012; Pappas et al., 2018; Tran and Beal, 2016; Wheat, 2009).

Candida serology

The only serological test currently useful for the diagnosis of invasive candidiasis is the Platelia® test, a sandwich enzyme-linked immunosorbent assay (ELISA), which detects mannan antigens, other sugars from *Candida* cell wall. However, this test has low sensitivity for the diagnosis of invasive candidiasis (Mikulska et al., 2010). To overcome this caveat, diagnostic accuracy can be improved by the use of another indirect ELISA test which detects circulating anti-mannan antibodies. The combination of the two tests' mannan antigens and anti-mannan antibodies gives sensitivity of 83% and specificity of 86% in acute disseminated candidiasis. Sensitivity is better for *C. albicans* compared to *C. glabrata* and *C. tropicalis*. The combined test has the advantage of being positive about 5 days before blood cultures. It is recommended by ESCMID for the diagnosis of candidemia and CDC, while BDG can be used for any type of invasive candidiasis (Cuenca-Estrella et al., 2012).

Other diagnostic tools

Polymerase chain reactions (PCR) are under evaluation. Sensitivity and specificity are variable depending on the studies, type of PCR (standard, nested, quantitative), target (rRNA, cytochrome P450 ...), and type of sample (serum, tissue, etc.). Results are obtained earlier than with other diagnostic tools. There is a risk of false positives due to contamination with saprophytic fungal species or to similarities between human and fungal DNA (Pappas et al., 2018). There is also a risk of false negatives due to the usual low number of fungal cells in the blood. In addition, the presence of a fungal cell wall limits access to DNA (Clancy and Nguyen, 2018; Cleveland et al., 2015; Moran et al., 2009; Wang et al., 2015). Despite the promising results demonstrated in a meta-analysis on 54 studies (Avni et al., 2011), due to lack of standardization the use of PCRs remains limited today in diagnosis of invasive candidiasis. Only positive results are reliable, negative results do not rule out infection.
